Hubble Space Telescope: Technical Specifications

The Hubble Space Telescope (HST) (figure 1) is a cooperative project between the US National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA). Designed to cover the wavelengths between approximately 0.1 and 3μm, from the near-ultraviolet through the visible to the near-infrared portions of the spectrum, it was launched on 25 April 1990, the first of NASA's 'Great Observatories'. It is operated as a general-purpose observatory capable of observing almost all celestial objects from the solar system to the distant universe. Access to the observing time is granted using peer review of proposals solicited competitively on a yearly basis without restriction on who can apply.

HST contains an $f/24$ Ritchey–Chretien reflecting telescope with a 2.4 m diameter primary mirror and five astronomical instruments that are designed to be replaced in orbit. The entire spacecraft has a cylindrical shape, 13.1 m long and 4.3 m in diameter at its widest point, not including the solar arrays, and has a mass of 11.6 t.

HST's instruments are modules that reside in separate compartments at the telescope focal plane (figure 2). The *radial instrument* is perpendicular to the optical axis with a pick-off mirror on the optical axis. The *axial instruments* are in four bays surrounding the optical axis. There are three additional sectors outside the optical axis that contain the fine guidance sensors (FGSs), which are used to point and stabilize the telescope by measuring the precise positions of field stars. The high accuracy of the FGSs for measurement of relative

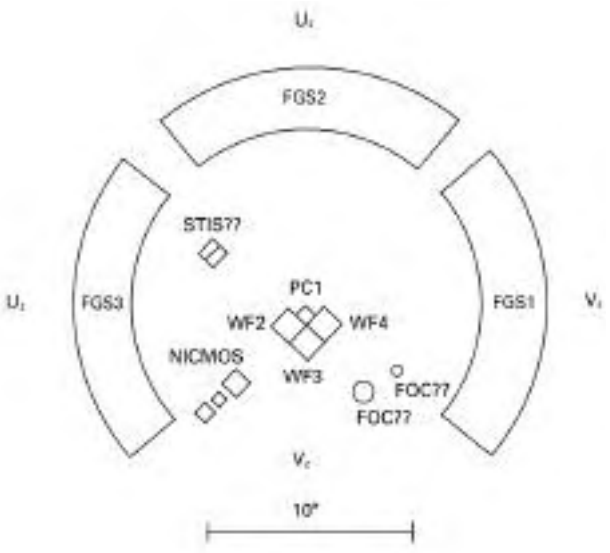

Figure 2. The different shapes show where the different instruments observe the sky relative to one another in the focal plane of the telescope. The three FGSs can observe over three-quarters of a ring surrounding the optic axis. Because the other instruments sample different parts of the focal plane, several instruments can be used simultaneously for parallel observing. The bar at the bottom of the figure is 10minutes of arc in length.

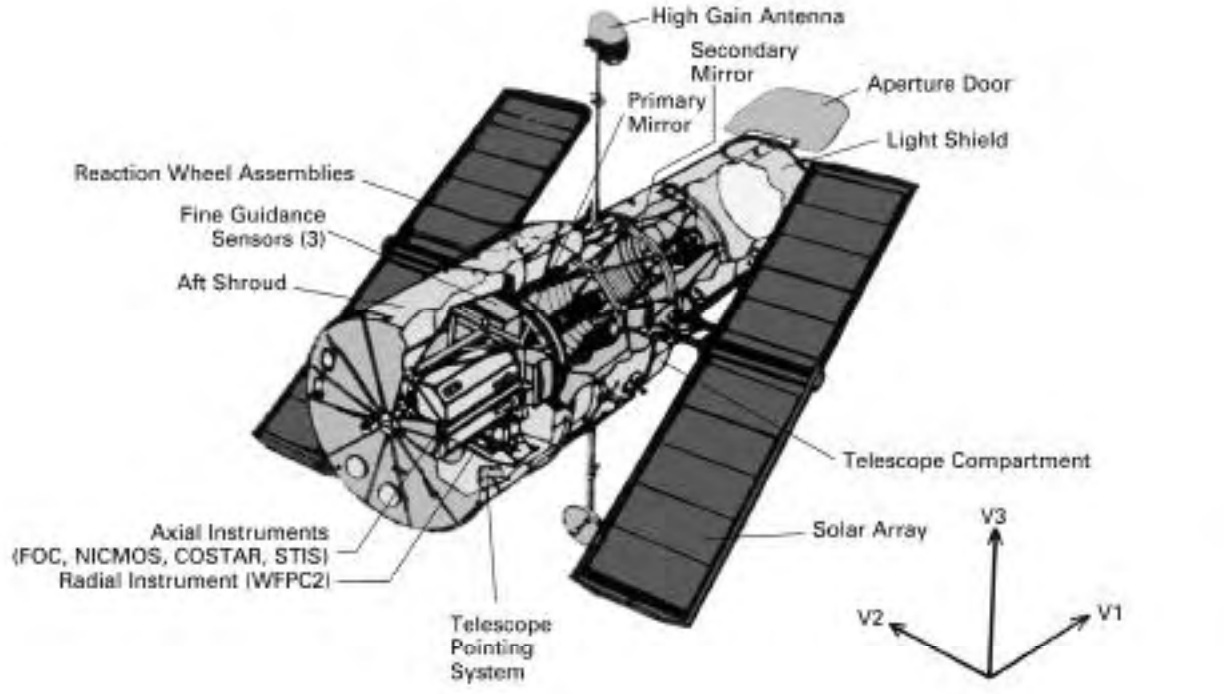

Figure 1. This schematic diagram of HST shows the key elements of the spacecraft.

positions of stars allows them to be used as a sixth instrument for astrometry.

HST is in a circular orbit approximately 600 km above the Earth, at an inclination of 28.5° relative to the Earth's equator. It has an orbital period of 96.4 min. Its low orbit makes it accessible to visits by astronauts in *servicing missions*. During a servicing mission, the astronauts can replace the instruments, upgrade spacecraft components such as computers, repair faulty hardware and electronics, and boost the telescope to a higher orbit to offset its rate of descent of 0.4 km/yr. There have been servicing missions in 1993, 1997 and 1999, and two more are planned for 2002 and 2004.

The current complement of instruments in addition to the fine guidance sensors includes the Wide Field and Planetary Camera 2 (WFPC2, radial), the Space Telescope Imaging Spectrometer (STIS, axial), the Faint Object Camera (FOC, axial), and the Near Infrared Camera and Multi-Object Spectrometer (NICMOS, axial). The fourth axial instrument bay contains the Corrective Optics for Space Telescope Axial Replacement (COSTAR), a set of optics that correct aberrations of the primary mirror for the FOC. NICMOS stopped functioning in 1998 following the exhaustion of its solid nitrogen cryogen used to cool the detector and optics. In the servicing mission planned for 2002, the FOC will be replaced by the Advanced Camera for Surveys (ACS, axial), and the NICMOS Cooling System (NCS), a mechanical cooler, will be installed to restore functioning of the NICMOS. In the 2004 mission, the WFPC2 will be replaced by the Wide Field Camera 3 (WFC3, radial), and the COSTAR will be replaced by the Cosmic Origins Spectrograph (COS, axial).

HST was launched with a primary mirror figured to the wrong focal length, so the images in the initial instruments were severely degraded by spherical aberration. The original solar panels providing power for the spacecraft vibrated at day or night entry, making it difficult to maintain accurate pointing for precise observations at those times. The first servicing mission replaced the main axial instrument, the Wide Field and Planetary Camera (WFPC), with WFPC2, an improved version fitted with optics to correct the spherical aberration of the primary mirror. COSTAR replaced one of the original radial instruments, the High Speed Photometer, and corrected the images for the other radial instruments. The corrections restored HST to its full imaging capability, with image quality limited only by diffraction from the primary mirror. A new set of solar panels eliminated the vibrations that kept HST from maintaining its pointing accuracy.

HST maintains pointing stabilization to better than 7 milliseconds of arc and absolute pointing better than 1 second of arc. It uses an elaborate system for attitude control to achieve this accuracy. Six gyroscopes provide an inertial frame of reference that allows HST to make an initial pointing accurate to a few tens of seconds of arc. Subsequently the fine guidance sensors lock onto stars and provide very precise pointing information to the control system to stabilize the spacecraft to its highest accuracy. Reaction wheels change the orientation of the spacecraft in space in response to commands from the attitude control system. HST also contains magnetometers that sense the direction of the Earth's magnetic field; they can be used to orient the spacecraft very crudely to keep it pointed away from the Sun in case the gyroscopes fail.

Following the correction of the optics during the 1993 servicing mission, HST enjoyed success as NASA and ESA's most important mission measured by scientific and public impact. It has made discoveries in almost every field of astrophysics from the nearest to the most distant celestial objects. Free from the distorting effects of the Earth's atmosphere, HST yields images of unrivalled resolution and clarity, many of which have become public icons.

Hubble, Edwin Powell (1889–1953)

Astronomer, born in Marshfield, MO, trained as a lawyer, with a Rhodes scholarship to Oxford University. Switched to astronomy at the University of Chicago, and became a staff astronomer at Mount Wilson Observatory where he had access to the best telescope in the world at that time—the 100 in telescope. Hubble was regarded as an aloof scientist, and, by contrast say to FRED HOYLE, did not speculate about the meaning of his discoveries, about the evolution of the universe or its origin in a 'creation event'. In fact he could be regarded as unimaginative, his work being characterized by a gathering of information from which he drew conclusions, as Francis Bacon would have done. Perhaps for this very reason the four discoveries that he made between 1922 and 1936 not only changed our view of the universe, but also endured. In the first part of this period, he proposed a classification system for nebulae, both what we would now describe as galactic and extragalactic nebulae. He recognized both emission nebulae (shining by their intrinsic emission) and reflection nebulae (redirecting the light of an associated star). He divided extragalactic nebulae into the now-standard classification system of *Hubble galaxy types*—elliptical, spiral and irregular galaxies arranged in a scheme known as the *Hubble tuning fork diagram*. In fact, with his discovery of Cepheid variable stars in NGC 6822, M33 and M31, he demonstrated the nature of extragalactic nebulae as collections of stars comparable to our own Milky Way (what we now call galaxies) at great distances. This settled a question that had been argued between CURTIS, Lundmark, SHAPLEY and ÖPIK, to name only four. He then showed that the distribution of galaxies was uniform, and they occupy a space that is cosmological. Finally, and most importantly, working with HUMASON, Hubble showed in 1929 that galaxies are moving away from us with a speed proportional to their distance (*Hubble's law*). The explanation led to the discovery of the expanding Universe. The slope of the *Hubble diagram* of the velocities of galaxies plotted against their distances is known as the *Hubble constant*, and its reciprocal, the *Hubble time*, is an estimate of the age of the universe. Hubble summarized his discoveries in a successful popular book *The Realm of the Nebulae*. He is commemorated by the name of the Hubble Space Telescope, which continues his investigations with modern space equipment.

Hubble's Variable Nebula (NGC 2261)

A reflection nebula in the constellation Monoceros, position RA $06^{h}\ 39.2^{m}$, dec. $+08^{\circ}\ 44'$. It is small ($2'$ by $1'$) but of quite high surface brightness. The nebula's average magnitude is 10, but, as Edwin Hubble discovered in 1916, it varies in brightness, mirroring the variability of its illuminating star, R Monocerotis.

Huggins, Margaret Lindsay Murray (1848–1915)

Astronomer, whose early interest in astronomy, taught to her by her grandfather, led to a meeting with and marriage to WILLIAM HUGGINS, a spectroscopist. Together they produced some of the earliest spectra of astronomical objects, particularly the Orion nebula.

Huggins, Sir William (1824–1910)

Astronomer, born in Stoke Newington, London, a wealthy amateur who built an observatory where he invented the stellar spectroscope. Building on KIRCHHOFF's and Bunsen's discoveries about terrestrial and solar spectral emission and absorption lines, and their conclusions that spectroscopy could reveal the composition of the source of the light, Huggins compared laboratory spectra with those of stars. At first he examined the spectra of astronomical sources visually. In 1875, after many experiments frustrated by the faintness of the stars and the insensitivity of the available photographic material, he recorded the spectrum of Vega on a dry gelatine plate. He explored the spectroscopic nature of stars, nebulae and comets. He showed that some nebulae, including the Orion nebula, have pure emission-line spectra and thus must be truly gaseous, while others, such as that in Andromeda, have continuous spectra characteristic of stars. He observed the spectrum of a nova and discovered that comets emit the light of luminescent carbon gas. He imaged solar prominences in monochromatic Hα emission by aligning a high-dispersion spectrograph slit tangent to the Sun's disc and gradually opening the slit. With Miller in 1868 he made the first measurement of the Doppler shift in a star.

Hulse, Russell A (1950–)

Radioastronomer and plasma physicist, born in New York City, Nobel prizewinner in physics with JOSEPH H TAYLOR (1993) 'for the discovery of a new type of pulsar, a discovery that has opened up new possibilities for the study of gravitation'. Using the 300 m radio telescope at Arecibo in Puerto Rico, Taylor and his research student Hulse searched systematically for pulsars, discovering the one now known as PSR 1913 + 16 and the *Hulse–Taylor pulsar*. The pulsar, it transpired, is in orbit around another neutron star. Each star is the mass of the Sun but very small (ten kilometers in dimension), and they are a short distance from each other, only several times the Moon's distance from the Earth. Since their mutual gravitational pull is large, their orbit shows deviations from Newton's gravitational laws. In particular, it was found that the period of the orbit is declining at the rate of about 75 millionths of a second per year, because the pulsar system loses energy by emitting gravitational waves. The rate is fully consistent with the predictions of general relativity. This was the first, albeit indirect, proof of the existence of gravitational waves.

Hulst, Hendrik van de (1918–)

Dutch astronomer, born in Utrecht, became professor at Leiden. During the Second World War, because of the shortage of equipment, Dutch astronomers were confined to work in theoretical topics. JAN OORT (Leiden Observatory) realized that radio waves would be able to penetrate the dust of interstellar space and would reveal the structure of the Galaxy. He therefore set a student, van de Hulst, to determine theoretically what radio emission would come from hydrogen, the most abundant element in interstellar space, indeed in the universe. Van de Hulst showed that the strongest emission from hydrogen in the radio spectral region would arise as a result of a spontaneous change of direction of spin from the electron orbiting a neutral hydrogen atom. In any given atom the change would occur once in millions of years, but there are so many neutral hydrogen atoms in space that the cumulative effect is very significant. The prediction of radio emission at a wavelength of 21 cm was confirmed by van der Hulst, Jan Oort and C Alex Muller in 1951, and the discovery matched Oort's expectations.

Humason, Milton La Salle (1891–1972)

American astronomer, born in Dodge Center, MN, who began his astronomical career as a muleteer and janitor at the Mount Wilson Observatory, and became a night assistant. He learnt photography and became HUBBLE's research assistant and then an astronomer in his own right, measuring the speeds of faint galaxies, and the properties of the supernovae in them.

Humboldt, Alexander von (1769–1859)

Naturalist, geographer, explorer, born in Tegel Palace, Berlin. The *Humboldt current* off the west coast of South America is named after him. He named the gegenschein. He set in train an international project organized by GAUSS to study terrestrial magnetism. His major work, *Kosmos*, based on lectures at Berlin University, endeavoured to provide a comprehensive physical picture of the universe. In it he described the results of the survey of terrestrial magnetism, and, in a particularly influential section, he drew attention to the observations of the Sun made by HEINRICH SCHWABE of the sunspot cycle. Humboldt's description of Schwabe's work provoked numerous follow-up studies (*see* JOHANN WOLF, EDWARD SABINE).

Huygens, Christiaan (1629–95)

Born in The Hague, Netherlands, to a prominent Dutch family, tutored at home, and came under the influence of DESCARTES who was an occasional visitor at the Huygens' home. Studied law and mathematics at Leiden, turned to scientific studies of nature. Made microscopes and telescopes, and in 1655, using one of his own lenses, Huygens detected Titan, the first moon of Saturn. He discovered the true shape of the rings of Saturn with one of his telescopes with a focal length of 7 m, and in *Systema Saturnium* (1659), explained the changes in the apparent shape of the rings. His telescopes, of enormous focal length, with the objective lenses supported on masts, were so far in advance of the rest of the field that at first his observations were not believed. In 1656 Huygens patented the first pendulum clock, testing models at sea to determine longitude. He also derived the law of centrifugal force for uniform circular motion, which in combination with Kepler's third law led WREN, HALLEY and others to the inverse square law of gravitation. Huygens proved by experiment the conservation of momentum, such that the momentum before the collision of two bodies is equal to the momentum after. In his *Traité de la Lumiere* Huygens argued in favor of a wave theory of light, stating that an expanding sphere of light behaves as if each point on the wave front were a new source of radiation of the same frequency and phase. In the final years of his life Huygens composed his book *Cosmotheoros*, published posthumously, apparently regarding it as a more scientific version of FONTENELLE's discussion of extraterrestrial life. It is a discussion that on the whole a modern astronomer can identify with. The Huygens probe that will eject from the Cassini spacecraft and parachute to the surface of Titan in 2004 is named for him.

Hydra

(the Water-snake; abbrev. Hya, gen. Hydrae; area 1303 sq. deg.) A predominantly southern constellation which winds its way around almost one-third of the sky between Canis Minor and Libra. The center of the constellation culminates at midnight in mid-March, though part of it is on the meridian from late January to early May. It represents, in Greek mythology, either the multi-headed Lernaean Hydra which was killed by Hercules as the second of his 12 labors, or the water-snake that prevents Corvus, the Crow, from drinking from Crater, the cup of the god Apollo. The brightest stars of Hydra were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*. Owing to its great extent, some early celestial cartographers divided Hydra into four divisions: Hydra, Hydra et Crater, Hydra et Corvus and Continuatio Hydrae.

Hydra is the largest of the 88 constellations but is not particularly prominent. Its brightest stars are α Hydrae (Alphard), magnitude 2.0, γ Hydrae, magnitude 3.0, and ζ Hydrae and ν Hydrae, both magnitude 3.1. There are eight other stars brighter than fourth magnitude. Interesting stars include ε Hydrae, a multiple system, consisting of yellow (G5 and F7) components, magnitudes 3.8 and 7.8, separation 3″, the former of which has a close (white, A8) companion, magnitude 4.7, separation 0.2″, period 15 years, the latter of which has an unseen companion, period 9.9 days, and a fifth component, magnitude 12.7, separation 19″, and R Hydrae, a Mira-type variable (range 3.5–10.9, period about 389 days).

Other interesting objects in Hydra include M48 (NGC 2548), an open cluster of several dozen stars between ninth and thirteenth magnitude, and M68 (NGC 4590), a globular cluster, NGC 3242 (the 'Ghost of Jupiter'), a bluish planetary nebula, and M83 (NGC 5236), a spiral galaxy, all of eighth magnitude.

Hydrodynamic Instabilities

Most of the universe is made of gas, over all scales ranging from the intergalactic medium to stars and giant planets. This fluid rarely remains in static equilibrium or in stationary motion—many forces and processes conspire to render it unstable. When it is unstable, it may oscillate more or less regularly around its equilibrium state, as do variable stars. Alternatively, it may reach a state of turbulent motion, which then plays a crucial role in transporting momentum, heat and chemicals and in amplifying a magnetic field when the gas is ionized. In some cases there is direct observational evidence for such turbulence: in the interstellar medium, at the surface of the Sun and of the giant planets, in the solar wind. More often only indirect proof of turbulence is available, as in accretion disks or in stellar photospheres and interiors.

To test the stability of any fluid medium in the universe, one applies to it an arbitrary perturbation—that is, one applies this perturbation to a mathematical model built with the equations of fluid dynamics (see FLUID DYNAMICS). Once perturbed, the fluid may settle back into its initial state, which is then deemed to be stable, or else the perturbation grows to finite amplitude, and the medium becomes turbulent or oscillatory. In the mathematical treatment, one makes a distinction between a linear instability, which is triggered by an exceedingly small perturbation, and a finite-amplitude instability, which requires a perturbation of a certain strength (depending on the degree of instability). However, for the description of the final state it does not much matter whether the instability is of either type.

Non-linear effects are required to prevent the infinite growth of any hydrodynamic instability. For example, turbulence acts always to suppress—at least to reduce—the cause of instability, in modifying for instance the mean flow profile (shear instabilities) or the temperature stratification (thermal convection). Numerical simulations have greatly helped to describe these finite amplitude regimes, but, even with present-day computers, the spatial resolution is often too limited for a realistic description.

Here we shall briefly review the main hydrodynamic instabilities encountered in astrophysics; we shall classify them according to their cause, describe their major properties and mention the objects where they presumably play an important role. We shall put more emphasis on recent results; for the others we refer the reader to classical treatises. Finally, we shall not discuss here the various instabilities involving a magnetic field, which are dealt with in MAGNETOHYDRODYNAMICS and ACCRETION DISKS.

Testing the linear stability

When the medium or the flow under consideration is submitted to a small perturbation, say a displacement $\delta\boldsymbol{r}(\boldsymbol{r},t)$ ($\boldsymbol{r}$ designates the spatial coordinate and t the time), then only the linear terms in $\delta\boldsymbol{r}$ may be kept in the equations describing the evolution of that perturbation. After some manipulations, the result may be cast in the general form

$$\left(\frac{\partial}{\partial t}-\mathcal{L}_1\right)\left(\frac{\partial}{\partial t}-\mathcal{L}_2\right)\cdots\left(\frac{\partial}{\partial t}-\mathcal{L}_n\right)\delta\boldsymbol{r}=0 \qquad (1)$$

where the $\mathcal{L}_i$ are linear spatial operators. Equation (1) admits separable solutions of the type

$$\delta\boldsymbol{r}(\boldsymbol{r},t)=\boldsymbol{A}(\boldsymbol{r})\exp(\sigma t)$$

and the vector function $\boldsymbol{A}$ obeys the partial differential equation (in space)

$$(\sigma-\mathcal{L}_1)(\sigma-\mathcal{L}_2)\ldots(\sigma-\mathcal{L}_n)\boldsymbol{A}(\boldsymbol{r})=\boldsymbol{0} \qquad (2)$$

which, after imposing suitable boundary conditions, constitutes an eigenvalue problem for σ. These eigenvalues depend on the spatial characteristics of the perturbation, such as its wavelength or the number of nodes. In simple cases, they are solutions of an algebraic equation of degree n, which is then called the dispersion relation. Examples of such relations are given below in equations (3) and (4).

In many cases, the eigenvalues σ are complex quantities; it is their real part $\mathcal{R}(\sigma)$ which determines the linear stability of the considered medium or flow. Instability arises whenever one of the eigenvalues has a positive real part.

Gravitational instabilities

Jeans instability

In most astrophysical objects, pressure forces balance the gravitational attraction. However, if the density (hence the mass) is too large, the medium may become unstable to infinitesimal perturbations. In a uniform medium, or locally in a non-uniform medium, the criterion for this instability takes the form

$$\sigma^2=4\pi G\rho-c_{\rm s}^2\left(\frac{2\pi}{\lambda}\right)^2\geq 0 \qquad (3)$$

where σ^2 is the exponential growth rate, $c_{\rm s}$ the isothermal sound speed ($c_{\rm s}^2=P/\rho$ in terms of pressure and density), G the gravitational constant and λ the wavelength of the perturbation. Setting $\sigma=0$ one obtains a critical wavelength $\lambda_{\rm J}$ and a critical mass $M_{\rm J}\approx\rho\lambda_{\rm J}^3$. If the medium is already turbulent for another reason, the turbulent pressure acts to increase the critical mass. So does also a magnetic field, when present.

In a uniformly rotating flow, the criterion includes a Coriolis term:

$$\sigma^2=4\pi G\rho-c_{\rm s}^2\left(\frac{2\pi}{\lambda}\right)^2-4\Omega^2\geq 0.$$

With differential rotation, as in a galactic disk, and assuming that all the mass is concentrated in the equatorial

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

plane, the instability criterion involves the epicyclic frequency Ω_{ec} (Toomre 1964):

$$\sigma^2 = 2\pi G\Sigma\frac{2\pi}{\lambda} - 4\Omega_{ec}^2 \geq 0 \qquad \Omega_{ec}^2 = \frac{1}{s^3}\frac{d}{ds}(s^2\Omega)^2 \quad (4)$$

with Σ being the surface density and s the distance from the rotation axis.

The Jeans instability is probably the main cause of star formation in the interstellar medium; the dynamical phase of the contraction ends when the gas becomes opaque enough to build up a temperature gradient: the associated pressure gradient is then able to balance the gravitational attraction.

Rayleigh–Taylor instability
This instability arises when denser fluid is superposed on lighter fluid in a gravitational field or an accelerating medium. It plays a crucial role in mixing chemical species during supernova explosions. A detailed description may be found in FLUID DYNAMICS.

Shear instabilities

Kelvin–Helmholtz instability
In this prototype of all shear instabilities, two parallel flows of different velocities V_1 and V_2 are separated by a sharp interface: if the interface is perturbed by an infinitesimal amount, all downstream wavelengths are unstable. When the transition layer between the two flows has a finite width H in z, only the wavelengths larger than $\approx H$ are unstable. This result holds also for a smooth velocity profile $V_x(z)$, containing an inflection point at which the vorticity dV_x/dz has a local extremum of width H (see figure 1); this instability condition is called the Rayleigh-Fjørtøft criterion. The instability domain is further reduced when the viscosity (ν) is taken into account; the instability occurs if the Reynolds number is larger than unity, with this number being defined as

$$\mathrm{Re} = \frac{H^2}{\nu}\left|\frac{dV_x}{dz}\right|_{max} \quad (5)$$

where $|dV_x/dz|_{max}$ measures the vorticity contrast. This plain Kelvin–Helmholtz instability is likely to occur in ASTROPHYSICAL JETS.

Even in the absence of a such a vorticity extremum, a parallel shear flow becomes unstable to perturbations of finite amplitude, but at much higher Reynolds number, as demonstrated by many laboratory experiments. In channel flows, the critical Reynolds number is found around 1000, with H being the channel width and replacing the vorticity contrast in the definition above by a measure of the vorticity itself.

Shear instability in a stratified medium
When an incompressible shear flow is stratified in density (in z, the cross-stream direction), buoyancy acts to inhibit the instability. Neglecting dissipative effects, instability sets in only if the Richardson criterion is met:

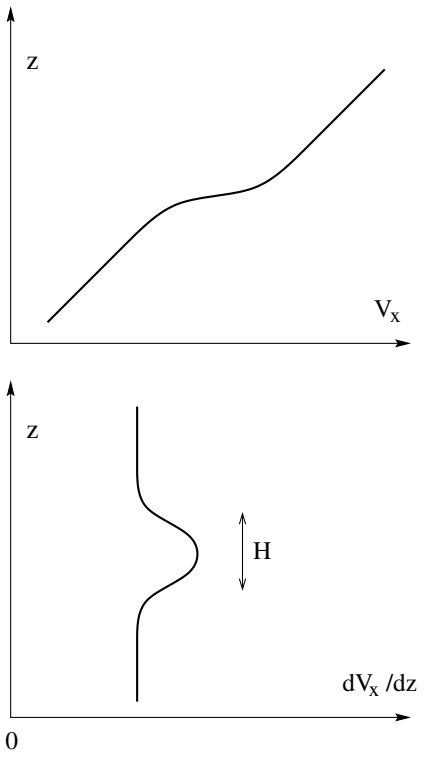

Figure 1. Plane parallel shear flow: the velocity vector is parallel to the x-axis and it varies in the (span-wise) z-direction. In this example, the velocity profile has an inflection point where the vorticity dV_x/dz is extremum: according to the Rayleigh-Fjørtøft criterion, this flow is linearly unstable.

$$\mathrm{Ri} = \frac{N^2}{|dV_x/dz|^2} \leq \mathrm{Ri}_c \qquad N^2 = -g\frac{d\ln\rho}{dz} \quad (6)$$

where N is the buoyancy frequency, which measures the stability of the density stratification (g is the acceleration due to gravity). The critical Richardson number $\mathrm{Ri_c}$ is of order unity.

Astrophysical fluids are compressible in general, and there the entropy stratification plays the role of the density stratification for incompressible fluids. The buoyancy frequency is then defined as

$$N_T^2 = \frac{g\delta}{H_P}\left[\frac{d\ln T}{d\ln P} - \left(\frac{\partial\ln T}{\partial\ln P}\right)_{ad}\right] = \frac{g\delta}{H_P}(\nabla - \nabla_{ad}) \quad (7)$$

with $\delta = -(\partial\ln\rho/\partial\ln T)_P$, H_P being the pressure scale height, and the notations used in stellar structure theory for the actual (∇) and adiabatic (∇_{ad}) temperature gradients having been introduced. Note that the stabilizing effect of the entropy stratification is felt only in the vertical direction: it does not prevent a horizontal shear from becoming unstable. In the latter case the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

turbulent motions are anisotropic, i.e. much stronger in the horizontal than in the vertical direction.

However, this instability criterion (6) applies only for adiabatic perturbations. In the presence of thermal diffusion (due to conduction or radiation), the buoyancy force weakens, and therefore also its stabilizing effect. The outcome is that the flow may sustain turbulence as soon as

$$\frac{N_T^2}{|\mathrm{d}V_x/\mathrm{d}z|^2}\frac{v\ell}{K} \leq \mathrm{Ri_c} \tag{8}$$

where v is the root mean square velocity, ℓ the dimension of the largest turbulent eddies and K the thermal diffusivity. These motions will carry heat and chemicals across the flow in the z-direction, with a turbulent diffusivity

$$D_\mathrm{t} \approx K\frac{|\mathrm{d}V_x/\mathrm{d}z|^2}{N_T^2}.$$

So far we have assumed that the fluid is homogeneous. A chemical composition gradient, with molecular weight μ increasing with depth, will also act to stabilize the flow, and one retrieves the original Richardson criterion (6) with

$$N^2 = N_\mu^2 = \frac{g\varphi}{H_P}\frac{\mathrm{d}\ln\mu}{\mathrm{d}\ln P} \qquad \varphi = \left(\frac{\partial\ln\rho}{\partial\ln\mu}\right)_{P,T}.$$

However, the stabilizing effect of this μ gradient may be drastically lowered if the horizontal shear is unstable, in which case the anisotropic turbulence acts to smooth out the horizontal inhomogeneities. The resultant turbulent diffusivity in the vertical direction then becomes (Talon and Zahn 1997)

$$D_\mathrm{t} \approx \frac{|\mathrm{d}V_x/\mathrm{d}z|^2}{N_T^2/(K+D_\mathrm{h})+N_\mu^2/D_\mathrm{h}}$$

where N_T^2 is the thermal component of the stratification as defined in equation (7) and D_h the horizontal diffusivity generated by the horizontal shear.

These shear instabilities certainly play an important role in the mixing of stably stratified stellar interiors.

Shear instability of differential rotation

Most of the results above can be transposed to differentially rotating flows. In cylindrical rotation, where the rotation rate depends only on the distance s from the rotation axis, an extremum of vorticity again renders the flow linearly unstable. Another linear instability arises when the angular momentum decreases with the distance from the rotation axis: a slight axisymmetric perturbation then grows because the pressure gradient no longer balances the centrifugal force (Rayleigh 1916). This instability has been studied in the laboratory with the famous Couette–Taylor experiment, where liquid is sheared between two concentric cylinders of mean radius s rotating at different speeds Ω_1 and Ω_2. Taking the gap Δs between cylinders as the characteristic length, one defines the Reynolds number as

$$\mathrm{Re} = \frac{s|\Omega_2-\Omega_1|\Delta s}{\nu}.$$

In the narrow gap limit, the critical Reynolds number for this linear instability is $\mathrm{Re_c} = 41.2(s/\Delta s)^{1/2}$, provided that $\Omega_1 s_1^2 > \Omega_2 s_2^2$.

However, even when $\Omega_1 s_1^2 < \Omega_2 s_2^2$, where the flow is linearly stable, turbulence has been observed for various rotation regimes, implying that the instability occurs at finite amplitude. There is still debate on whether a positive gradient of angular momentum is able to suppress hydrodynamic turbulence for certain flow profiles, such as in the Keplerian rotation of accretion disks. However, laboratory experiments seem to indicate that turbulence occurs whenever the gradient Reynolds number Re^* exceeds some critical value:

$$\mathrm{Re}^* = \frac{s^3}{\nu}\frac{\Delta\Omega}{\Delta s} \geq \mathrm{Re_c^*} \approx 6\times 10^5.$$

For a recent discussion of this problem we refer to Richard and Zahn (1999).

In objects such as stars and planets, a differential rotation in latitude becomes linearly unstable when the rotation profile meets certain conditions. For instance, when Ω varies in proportion to $1-a\cos^2\theta$ (θ being the colatitude), the flow is unstable to infinitesimal horizontal perturbations for $a > 0.29$ (Watson 1981).

Another instability, called baroclinic instability, may arise in stars whenever the rotation departs from cylindrical rotation, because the level surfaces (or isobares) do not coincide with the surfaces of equal density, and hence of equal entropy, in a homogeneous star. One is then tempted to conclude that an axisymmetric displacement directed sideways, in the wedge between these two surfaces, will escape the restoring action of the buoyancy force, and therefore lead to instability. However, such a displacement cannot be entirely arbitrary: it has to conserve angular momentum. When this is taken in account, one finds that the baroclinic instability occurs only when the specific angular momentum $\Omega r^2\sin^2\theta$ increases towards the equator on an isentropic surface.

However, this condition has been derived by assuming that the perturbations were adiabatic. Thermal diffusion will here again weaken the buoyancy force, and since in stellar interiors the viscosity ν is much smaller than the thermal conductivity K, axisymmetric perturbations will become unstable as soon as either

$$\frac{1}{s^3}\frac{\partial}{\partial s}(\Omega s^2)^2 < \frac{\nu}{K}N_T^2 \qquad \text{or} \qquad \left|s\frac{\partial\Omega}{\partial z}\right| > \frac{\nu}{K}N_T^2.$$

This so-called Goldreich–Schubert–Fricke instability belongs to the class of multidiffusive instabilities, which arise because two agents (here heat and momentum) diffuse at sufficiently different rates. Until now it has still not been

clarified whether this instability will lead to turbulence and mixing once it reaches its finite-amplitude regime.

On the other hand, any differential rotation is prone to shear instabilities of finite amplitude, as has been mentioned earlier: the situation is then very much like that of plane parallel shear, and the results quoted above apply. The horizontal shear of differential rotation in latitude will easily become unstable, since the Reynolds number characterizing such flows is extremely high ($\mathrm{Re}^* \approx 10^{15}$ at the base of the solar convection zone). A stable entropy stratification will inhibit the vertical shear instabilities, but only to some extent, as has already been explained: it suffices to express the vertical shear $|\mathrm{d}V_x/\mathrm{d}z|$ by $r \sin\theta \, \mathrm{d}\Omega/\mathrm{d}r$. These instabilities certainly play an important role in the mixing of stably stratified stellar interiors (Zahn 1992).

Thermal instabilities

Convection

A temperature gradient is required to transport heat through a conductive or optically thick medium, and often this gradient is parallel to the gravity force, as illustrated in stars and accretion disks. In terms of the heat flux F and of the thermal diffusivity K, this temperature gradient is given by

$$F = K \frac{\rho C_P T}{H_P} \left(\frac{\mathrm{d} \ln T}{\mathrm{d} \ln P} \right) \tag{9}$$

(C_P is the heat capacity at constant pressure). In such a stratification, a vertical perturbation will grow if it rises in colder surroundings, and this will lead to a familiar instability called thermal convection. This (linear) instability sets in when the Schwarzschild criterion is satisfied:

$$\frac{\mathrm{d} \ln T}{\mathrm{d} \ln P} > \left(\frac{\partial \ln T}{\partial \ln P} \right)_{\mathrm{ad}}$$

or in the classical notation of stellar structure theory, $\nabla > \nabla_{\mathrm{ad}}$ (small corrections apply when including the effect of thermal and viscous dissipation). ∇_{ad} measures the temperature increase in an adiabatic compression. The temperature gradient then tends to become adiabatic, and a fraction of the heat flux is transported through the convective motions. In astrophysical settings these motions are turbulent, and at sufficient optical depth the energy flux is given by

$$F_{\mathrm{conv}} \approx v\ell \frac{\rho C_P T}{H_P} (\nabla - \nabla_{\mathrm{ad}}).$$

Defining the radiative gradient ∇_{rad} as the gradient which would be needed to carry the total flux F_{tot} through conduction or radiation (cf equation (9)), the conservation of flux $F_{\mathrm{tot}} = F_{\mathrm{conv}} + F_{\mathrm{rad}}$ translates into

$$\frac{\nabla_{\mathrm{rad}} - \nabla}{\nabla - \nabla_{\mathrm{ad}}} = \frac{v\ell}{K}.$$

The higher the Péclet number $v\ell/K$, the closer the temperature gradient comes to being adiabatic (at the base of the solar convection zone, $v\ell/K \approx 10^6$). A prescription is needed to estimate the turbulent diffusivity $v\ell$, and the classical mixing-length treatment is still widely used, for lack of something better: one assumes that the convective eddies are accelerated over a distance Λ (the mixing length), after which they dissolve in the surrounding medium where they release their heat content. For most purposes, the mixing length is taken as proportional to the local pressure scale height.

Great progress has been achieved already with three-dimensional numerical simulations, but the range of scales which has to be spanned is challenging, and these simulations are necessarily restricted to a small physical domain (near the surface of the star for instance) or to the largest motion scales (when the goal is to encompass a whole convection zone).

κ-Mechanism

In stellar interiors, the opacity peaks in the ionization zones of the most abundant species; there radiative diffusion is then no longer a dissipative process, and oscillations of the star grow owing to a valve mechanism. This thermal oscillatory instability is the cause of the pulsation of most variable stars (see STELLAR PULSATION).

Eddington–Sweet circulation

The centrifugal distortion makes it impossible, in general, to achieve radiative equilibrium in a rotating star, and the resulting thermal imbalance induces a large-scale meridian flow throughout the radiation zone. The time-scale for this Eddington–Sweet circulation is:

$$t_{\mathrm{ES}} = t_{\mathrm{KH}} \left(\frac{\Omega^2 R^3}{GM} \right)^{-1} \qquad t_{\mathrm{KH}} = \frac{GM^2}{RL}$$

where M, R and L are the mass, radius and luminosity of the star and t_{KH} is the Kelvin–Helmholtz time governing the global thermal adjustment. This time-scale is very large: only rapidly rotating stars will feel the effect of that circulation, which is then potentially able to mix them. This circulation also transports angular momentum, and it tends to establish a rotation profile for which there would be no circulation at all, and hence no mixing. However, for several reasons this regime of complete rest is never attained: (i) most often the vertical shear is unstable, and turbulence generates its own transport of angular momentum; (ii) the star loses angular momentum carried away by a wind; (iii) while evolving, and hence contracting or expanding, the star alters its internal angular momentum distribution (cf Zahn 1992).

More seriously, the vertical composition gradient which builds up through nuclear burning interferes with the circulation and acts to slow it down. Presumably it will not succeed in suppressing it altogether (Maeder and Zahn 1998). However, we are still in great need of a realistic description of the turbulence arising in such a stratified, differentially rotating star to properly assess the amount of mixing.

Hydrogen (H)

The lightest and most common element in the universe. About 92% by number of atoms, and about 75% by mass, of all the directly observed matter in the universe is hydrogen. The most common form of hydrogen atom consists of one positively charged particle, the proton, and one negatively charged particle, the electron, which orbits the proton. The atomic mass is 1 and the atomic number (i.e. charge on the nucleus) is also 1. Hydrogen nuclei exist with one or two neutrons in addition to the one proton. These forms of 'heavy hydrogen' are called deuterium and tritium, respectively. Regions of neutral hydrogen are referred to as HI regions. Regions of ionized hydrogen are HII regions.

Hydrogen Spectrum

The series of absorption or emission lines that are characteristic of the hydrogen atom. According to the Bohr theory of the hydrogen atom, devised by Danish physicist Neils Bohr (1885–1962) in 1913, the hydrogen atom can be envisaged as consisting of a central nucleus (a proton) around which a single electron revolves. The electron is located in one of a number of possible permitted orbits, each of which corresponds to a different energy level. If an electron drops down from a higher to a lower level (makes a 'downward transition'), energy is emitted in the form of a photon, the energy of which is equal to the difference in energy between the two levels. Conversely, if an electron absorbs a photon of the correct energy, it can make an upward transition from a lower to a higher level. Because a photon of a particular energy corresponds to light of a particular wavelength, the various downward, or upward, permitted transitions correspond to the emission, or absorption, of particular wavelengths of light. This mechanism is responsible for the production of the various lines in the hydrogen spectrum.

In the hydrogen atom, the various energy levels are denoted by a number (a quantum number), n; $n = 1$ corresponding to the lowest level, $n = 2$ to the second level (the first 'excited' level), $n = 3$ to the third level (the second excited level), and so on. The wavelength, λ, of the line that is produced by a transition between a lower level, n, and a higher level, m, is given, in nanometers, by the following formula: $\lambda = 91.16/(\frac{1}{n^2} - \frac{1}{m^2})$. For example, a transition between $n = 2$ and $n = 3$ gives rise to a line of wavelength $\lambda = 91.16/(\frac{1}{2^2} - \frac{1}{3^2}) = 91.16/(\frac{1}{4} - \frac{1}{9}) = 656.3$ nm. This line, which is called the hydrogen alpha (Hα) line, lies towards the red end of the visible spectrum and is the first in a series of lines, known as the Balmer series, which is produced by the various possible transitions between the $n = 2$ level and higher levels. The second line, Hβ, which occurs at a wavelength of 486.2 nm corresponds to transitions between the second and fourth levels ($n = 2$, $m = 4$), the third, Hγ, at 434.1 nm, and so on. The series comes to an end at 364.6 nm ($n = 2$, $m = \infty$), which corresponds to the electron being completely removed from the atom.

Transitions between the ground level ($n = 1$) and higher levels involve larger energy gaps and, because the energies of photons are inversely proportional to their wavelengths, give rise to lines of shorter wavelengths than those of the Balmer series. The resulting series of lines, which occur in the ultraviolet region of the spectrum, is called the Lyman series. The series begins with Lyman alpha, at 121.5 nm and ends at the series limit of 91.16 nm. Transitions between the third level ($n = 3$) and higher levels correspond to small energy gaps and give rise to the Paschen series, in the infrared region of the spectrum.

Hydrus

(the Little Water-snake; abbrev. Hyi, gen. Hydri; area 243 sq. deg.) A southern constellation which lies between Tucana and Horologium, and culminates at midnight in late October. It was first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, which lies between the Large and Small Magellanic Clouds, the brightest stars in Hydrus are β Hydri, magnitude 2.8, which is the closest conspicuous star to the south celestial pole, about 12° distant, α Hydri, magnitude 2.9, and γ Hydri, magnitude 3.3. There are no other stars brighter than fourth magnitude. Interesting objects include NGC 1466, an eleventh-magnitude globular cluster of the Large Magellanic Cloud, and NGC 1511, a small edge-on spiral galaxy, also eleventh magnitude.

Hygiea

The tenth asteroid to be discovered, by Annibale De Gasparis in 1849, and so designated (10) Hygiea. It is the fourth-largest asteroid, with a diameter of 408 km. It orbits the Sun at a mean distance of 3.14 AU (470 million km), in the outer part of the main asteroid belt, in a period of 5.55 years. The orbital inclination is 4, the eccentricity 0.12 and the rotation period an estimated 27.6 h. It is a C-type asteroid, with a reflectance spectrum very similar to that of carbonaceous chondrites, and has an albedo of 0.07.

Hypatia of Alexandria (370–415)

Born in Alexandria, Egypt, daughter of the mathematician and philosopher Theon, and the first woman mathematician of note. As head of the Platonist school at Alexandria, she symbolized the learning that early Christians identified with paganism, and became a focal point of riots during which she was brutally murdered, perhaps under the orders of Cyril, the fanatical Christian Patriarch of Alexandria. She wrote commentaries on algebra, arithmetic, conics and on PTOLEMY's astronomical works, all lost. She developed apparatus, including an astrolabe (for measuring the positions of the stars, planets and Sun).

Hyperbola

The conic section obtained when a right circular cone is cut by a plane which makes an angle with the base greater than that made by the side of the cone. It is an *open* curve, i.e. it does not close on itself like an ellipse.

See also: conic sections, ellipse, parabola.

Hyperion

A mid-sized icy satellite of Saturn, discovered by W C Bond and, independently, William Lassell, in 1848. It orbits at a distance of 1 481 000 km, and is an irregular object, measuring 330 by 260 by 220 km. Hyperion was probably once a larger object which suffered a number of near-catastrophic collisions. Most of the impact debris would have been swept up by Titan, but some would have peppered Rhea, giving the latter its heavily cratered surface. Hyperion has chaotic rotation: it tumbles along in its orbit instead of rotating about a single axis; this adds credence to the collision hypothesis. Its surface is heavily cratered, with a scarp over 200 km long named Bond–Lassell Dorsum in honor of the satellite's discoverers.

Iapetus

A mid-sized icy satellite of Saturn, discovered by Giovanni Cassini in 1671. It is 1440 km in diameter, and orbits at a distance of 3 561 000 km. Iapetus is unique in the solar system in its harlequin appearance: the leading hemisphere—facing the direction of orbital motion—is dark, with an albedo of around 0.05, while the trailing hemisphere is bright, with an albedo of 0.5. Its magnitude thus changes in the course of its orbit, as Cassini himself noticed, and he guessed correctly at the reason. It has been suggested that dust from Saturn's dark outer satellite Phoebe, thrown off by impacts, is spiraling inward and is swept up by Iapetus, which, like most of Saturn's satellites, has captured rotation, so that the dust would accumulate on the same (leading) hemisphere. It may be that Iapetus' surface ices contain methane, and when they are shock-heated by the impact of the dust particles, dark tarry organic substances are formed.

Ibn Rushd, Abu'l Waleed Muhammad Ibn Ahmad Ibn Muhammad [known as Averroes] (1128–98)

Islamic philosopher, lawyer, physician and astronomer, born in Cordoba, Spain, became physician to the Caliph of Morocco. Ibn Rushd's controversial views on philosophy—he was the greatest Islamic proponent of ARISTOTLE—led to the burning of his books and banishment by the Caliph. He wrote numerous books (87 survive) dealing with philosophy, logic, medicine, jurisprudence and astronomy, which were translated (his name westernized to Averroes, The Commentator) and were very influential on European medieval thought. In astronomy he wrote a *Treatise on the Motion of the Sphere*, *Kitab fi-Harakat al-Falak*, and a summary and commentary on PTOLEMY's *Almagest*. His Aristotelianism was retrogressive in that, admitting that developments of the Ptolemaic system such as epicyclic motion of the planets gave numerically more accurate results, he nevertheless held that only concentric spheres were perfect enough to make up the universe.

Ibn Sina, Abu Ali [known as Avicenna] (980–1037)

Islamic philosopher and scientist, born in Kharmaithen, near Bukhara (now Uzbekistan). Avicenna's life was marked by swings of fortune, from physician and favored scholar of a Samanid prince, to peripatetic country doctor when the Samanid regime fell. He became court physician in Hamadan (Iran), where he was for a time imprisoned as a political prisoner. He ended his life in a peaceful, contemplative retirement in Isfaham, where he completed his two most important works, *The Canon of Medicine* (the most influential single book in the history of medicine, identifying the manner of the spread of epidemics, including tuberculosis) and *The Book of Healing* (an encyclopedia covering the whole of the sciences). Avicenna observed Venus as a spot against the surface of the Sun, inferring that Venus must be closer to the Earth than the Sun. He was one of several Islamic authorities who stated, on no particular grounds, that the velocity of light is finite.

Icarus

An Apollo asteroid discovered by Walter Baade in 1949, designated (1566) Icarus. In 1968, when it passed just 0.04 AU from the Earth, it was observed by radar and found to be about 1 km in diameter and to rotate in 2.27 h. Icarus is one of only a handful of asteroids with a perihelion distance (0.19 AU) within the orbit of Mercury; aphelion is at 1.97 AU, and its mean distance from the Sun is 1.08 AU (161 million km). The inclination is 23° and the eccentricity 0.83. Icarus is classed as a potentially hazardous asteroid.

Ida

An asteroid discovered by Johann Palisa in 1884, designated (243) Ida. In August 1993 it became the second asteroid to be imaged in close-up from a spacecraft when the Galileo probe passed within 2400 km *en route* to Jupiter. Ida was found to be a heavily cratered object measuring $56 \times 24 \times 21$ km, possessing a small companion: the first confirmed asteroidal satellite. Named Dactyl, the satellite measures $1.6 \times 1.3 \times 1.0$ km. From Dactyl's orbital motion, Ida's density was found to be between 2.0 and 3.1 g cm^{-3}, consistent with a composition similar to that of ordinary chondrites, as suggested by its S-type reflectance spectrum. It orbits the Sun in the main asteroid belt at a mean distance of 2.86 AU (428 million km) in a period of 4.84 years; the orbital inclination is 1°, the eccentricity 0.04 and the rotation period 4.6 h.

Imaging Near-Earth Space

Space in the Earth's neighbourhood was studied remotely from the ground long before the space age began, mostly through observation of the AURORA, but also by radio investigation of the ionosphere (see PLANETARY IONOSPHERES) and the plasmasphere (the low-energy PLASMA region around the Earth) (see MAGNETOSPHERE OF EARTH: PLASMASPHERE). More recently, it has been studied mainly through direct *in situ* measurements of charged particles and electromagnetic fields. A major problem for remote sensing of plasmas is that protons neither emit nor scatter photons. The first views of Earth from space showed little evidence for the SOLAR WIND, radiation belts (see MAGNETOSPHERE OF EARTH: RADIATION BELTS), or plasmasphere that were discovered from early spacecraft measurements. When the Earth was viewed in Lyman-α ultraviolet light by the Apollo 16 mission, an extended hydrogen gas geocorona was evident, and there was even a hint of day–night asymmetry suggestive of an interaction with solar radiation. However, space views of telltale auroral displays made it clear that something fascinating was going on in space around the Earth. At the time, there was no simple means of obtaining images of the space plasmas responsible for these phenomena.

In the 1970s, measurements showed the existence of solar helium ion emissions scattered from helium ions in the plasmasphere. Analysis showed that the fluxes were sufficient to image the helium in this region using cameras of suitable response and sensitivity. In the 1980s, it was discovered that the energetic plasma regions around the Earth emit a glow of energetic neutral atoms (ENAs) (see ATOM). This results from charge exchange interactions between energetic ions and low-energy neutral gas atoms. At that point, scientists began to realize that, since fast neutral atoms radiate in nearly straight lines, they can serve much as photons can to form a flux image of their source regions. Together, these discoveries offered the opportunity to remotely sense and image diffuse space plasmas that are otherwise invisible. The ENA imaging concept was proven using instruments designed for charged particle measurements on the ISEE mission in the 1980s and the POLAR mission in the 1990s. A plan emerged for the development of the NASA Imager for Magnetopause to Aurora Global Exploration (IMAGE) in the late 1990s. Using all of the known plasma imaging techniques, IMAGE completed its first year of operations in May 2001, changing forever the way we view space plasma storms.

The SOHO mission's spectacular imagery of the Sun has provided dramatic evidence that it is anything but a quiescent and constant star. SOHO showed huge explosions launching billion-tonne coronal mass ejections (see SOLAR CORONAL MASS EJECTION) into the solar system at millions of kilometers per hour, some of which impact the Earth on their way to the heliopause. IMAGE has provided corresponding images of plasmas around the Earth and their response to the solar wind buffeting that they receive. Multispectral movies show the development of electron and ion auroras, as the solar wind scours the outer boundaries of the magnetosphere (see PLANETARY MAGNETOSPHERES) and enters into the dayside cusp regions. The ionosphere is seen to respond to auroral energy inputs by flowing out into space. Clouds of hot plasma form near midnight and drift rapidly as they encircle the Earth, inflating the geomagnetic field. The cold plasma near the Earth is swept sunward by the return flow through the centre of the magnetosphere. Finally, one sees the galactic gas flowing through the solar system, the remnant nebular dust disk (see NEBULA) and their interactions with the solar wind.

Instrumentation

The ENA glow from near-Earth space extends over several orders of magnitude in particle energy, requiring multiple imaging techniques. Energy and mass analysis of the neutral atoms is most effectively done using electrostatic deflection and time-of-flight measurements. Detection of secondary electrons produced on particle passage through thin carbon foils is an effective technique for recording the passage of a particle, yielding a time-of-flight start signal.

At energies greater than about 20 keV (greater for heavier species), neutral atoms will penetrate carbon foils that are thick enough to stop solar UV radiation, a significant contaminant signal. From 20 keV down to about 1 keV, neutral atoms can penetrate the thinnest carbon foils, but these foils do not stop UV radiation, so it is necessary to use sophisticated diffraction grating filters that stop very nearly all of the UV without stopping so large a fraction of the fast particles. In both higher-energy ranges, the subject of interest is the hot plasma that forms around the Earth, particularly during magnetospheric storms. This plasma carries the largest and longest-lived electrical current of such storms, known as the ring current because of its eventual encirclement of the Earth. Cameras for this energy range must have wide-angle fields of view, 120° or wider.

Below 1 keV, neutral atoms cannot penetrate even the thinnest carbon foils, so it is necessary first to convert the atoms into ions using interactions with other atoms, ideally to produce corresponding negative ions via electron attachment. Once charged, the atoms can be manipulated with electrostatic fields to measure their energy and accelerate them, and then time-of-flight methods can be used to determine their velocity or, knowing their energy, their mass. In this lowest energy range, the target of greatest interest may be the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

ionosphere itself, where plasmas are initially heated to a few tens of eV or higher, causing them to escape promptly from the Earth's gravity and flow into the magnetosphere. Cameras for this energy range may have somewhat smaller fields of view, but 90° or wider is highly desirable.

The scattered solar extreme UV (EUV) glow from near-Earth space originates from the atomically active cold helium ions of the ionosphere and its dense extension into the magnetosphere, known as the plasmasphere. This glow had been noted by some sounding rocket instruments and crudely imaged during Apollo mission flights to the Moon. The plasmasphere is generally contained within geomagnetic flux tubes extending at most about 4–5 Earth radii, requiring a wide-angle camera when viewed even from high-altitude Earth-orbiting spacecraft. Here again, a 120° field of view or larger is essential to encompass the object being imaged. Spectral coverage must be confined to the 30.4 nm line of He^+, which produces a substantial isotropic glow from the corresponding solar emission feature. The aurora is also active in this wavelength range, but, because of its very different morphology, will not be confused with plasmaspheric emissions.

The auroral far ultraviolet (FUV) glow is preferable to visible emissions for auroral imaging because it is relatively uncontaminated by light scattered from the sunlit parts of the auroral zone. The most useful wavelength as a measure of electron precipitation is the 135.6 nm line of oxygen, because it is scattered only very slightly and can be simply related to the energy flux of electron precipitation. Another bright line at 130.4 nm must be discriminated against because it is severely scattered and contaminated with airglow. In addition, energetic protons precipitating into the atmosphere in what is called the 'proton aurora' also emit FUV photons. These precipitating protons spend part of their time as fast neutral atoms as they begin to charge exchange with atmospheric atoms, some of which radiate in Doppler-shifted Lyman-α. These photons can be distinguished from others emitted by the cold atmospheric hydrogen by a space-based spectrographic imager capable of resolving the red shift of the precipitating keV protons as they move rapidly away from the instrument into the atmosphere. Imagers for auroral emissions can have much narrower fields of view (~15°), since the aurora is a relatively small feature of the magnetosphere, contained for the most part within the Earth's disk.

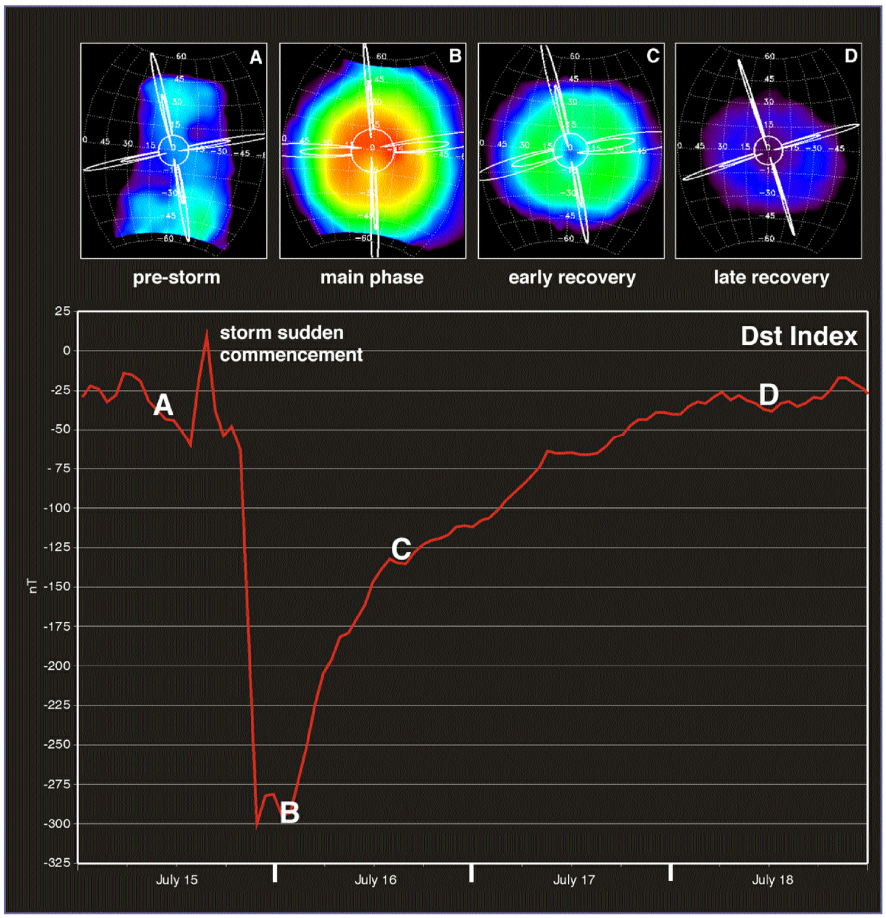

Figure 1. The development of ring current neutral atom glow during the overall development of a space plasma storm, as indicated by the concurrent variation of the equatorial geomagnetic field intensity (known as the storm time deflection, Dst).

An additional technique — strictly speaking a remote sensing technique — has proved useful for establishing quantitative calibrations of the EUV images, for detection of relatively fine-scale features and for sensing plasma density gradients at densities below the detection limit for EUV imaging. This is the radio plasma imaging (RPI) method, using extremely long wire antennas (hundreds of metres) to broadcast and receive radio wave pulses (3 kHz–3 MHz) reflected or refracted from plasma density gradients. This technique is closely related to ground-based ionospheric sounding observations and indeed represents a generalized topside-sounder method useful for sensing the plasmasphere and any other suitably oriented plasma density gradient structures in the magnetosphere.

Observations

Since its launch in late March 2000, IMAGE has provided a large quantity of new imaging data for near-Earth space, including magnetospheric dynamics as driven by solar storm events and some observations of the heliospheric environment including interstellar gas (see INTERSTELLAR MATTER) and remnant dust.

The ENAglow of the Earth contains many expected features and several new features that are still being interpreted and modeled. Figure 1 shows an example of the development of a relatively symmetric ENA glow encircling the Earth, representative of the corresponding cloud of energetic ions. Initially, the source of new particle injection fills the magnetosphere from the antisunward side by means of a relatively strong sunward plasma flow. Hot plasma particles that were injected then find themselves on stably trapped drift orbits that similarly encircle the Earth. With time, this hot plasma cloud decays away through a combination of processes, including losses into the atmosphere as well as the losses to charge exchange that permit these images to be recorded.

The Sun and solar wind are also sources of neutral atom glow. On its way to Earth, the solar wind passes through interstellar gas and an even smaller amount of gas emitted by dust particles in the inner solar system. As it arrives near Earth, it encounters a third gaseous charge exchange medium, the geocorona. Changes in solar wind intensity can be viewed from inside the magnetosphere as a brightening of the ENA glow from the solar wind interaction with the geocorona. Ionospheric plasma heating responds promptly to solar wind energy, causing the Earth to emit low-energy neutral atoms (LENAs), while the global storm response develops over somewhat longer time scales involving the magnetic tail. Figure 2 shows an example of LENA data illustrating simultaneous observation of LENA from the Sun, from the Earth and from the interstellar medium. Long-term variations serve as a probe of the interplanetary and interstellar gas medium.

In EUV, the plasmasphere was found to be detectable above a threshold He^+ density of about 30 cm^{-3} (where He^+ density is about 10% of total density). As shown in figure 3, this provides very useful imagery of the main body of the plasmasphere. This image, taken from a disturbed period, clearly shows the formation of a drainage plume of plasma extending from the dusk sector sunward toward noon. Such a feature was predicted over 30 yr ago, but *in situ* observations from single spacecraft were somewhat ambiguous regarding the presence of this feature and could also be interpreted as evidence for 'detached plasma regions' with no connection to the main body of the plasmasphere. A large number of other

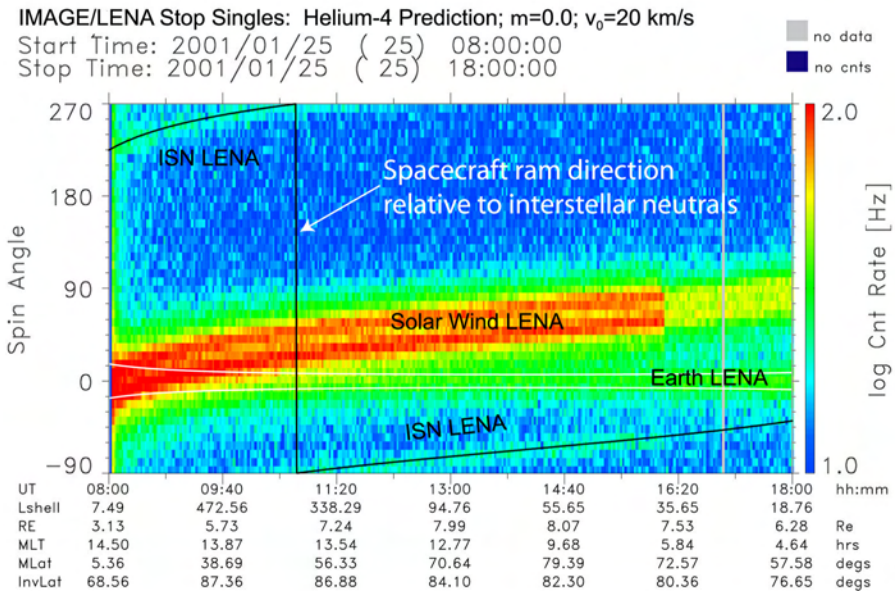

Figure 2. LENA glow from the Sun from the Earth, and from the interstellar gas, during several hours of the IMAGE orbit. Each vertical strip is formed by collapsing a 90° x 360° image in the 90° polar angle. White traces indicate the limbs of the Earth.

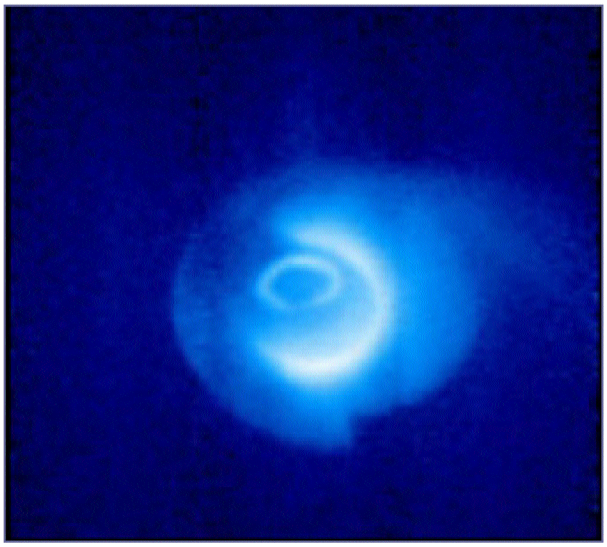

Figure 3. The EUV plasmasphere, illustrating drainage plume, shoulder and trough. The Sun's shadow provides a directional reference (toward upper left). EUV aurora and dayside ionospheric limb also appear in the image.

features have been identified in EUV imagery of the plasmasphere, including the shoulder and trough features visible in figure 3.

In FUV, IMAGE has provided valuable electron precipitation information that establishes storm context and connects with earlier auroral imaging efforts. In addition, the achievement of global Doppler-shifted proton imaging provides the first clear imagery of dayside solar wind interaction regions in which solar plasma entering the magnetospheric cusp regions is shown to be organized by interplanetary magnetic field orientation. Figure 4 illustrates the simultaneous electron / ion imaging capability and shows how different the morphologies of the two types of particle precipitation can be.

RPI obtains discrete echoes from the plasma of the topside ionosphere in the polar regions and near the plasmapause at lower latitudes. As illustrated in figure 5, echoes just inside the plasmasphere show that magnetic-field-aligned ducts exist and extend for distances of several Earth radii. Diffuse echoes from the plasmapause show that this boundary has a very irregular structure. When suitably inverted, these echo traces yield the distribution of plasma electron density for distances of 2–3 Earth radii along field lines linking the IMAGE spacecraft. These quantitative density measurements complement and serve to calibrate the EUV imagery.

Conclusions

The space environment of Earth has become an astronomical object in the sense that its component plasmas can now be remotely sensed and imaged as dynamic global structures. In another sense, the space environment contains dynamic meteorology and is an increasingly well-understood medium subject to global modeling and prediction. It can then be said that near-Earth space is the first plasma medium to be simultaneously studied using both plasma imaging and *in situ* techniques. Direct *in situ* measurements provide great detail in limited regions of space, with global structure emerging only over orbital evolution time scales. Plasma imaging produces a global perspective in the image accumulation time scale, but with modest spatial resolution. The best capabilities of the two observing techniques can now be exploited and validated against each other so as to strengthen the conclusions that can be drawn from either. The first year of operations of the IMAGE mission, in conjunction with other NASA spacecraft making *in situ* measurements, has confirmed the expected appearance of many features of near-Earth space, while revealing a number of new features that were either unexpected or previously undocumented.

Imbrium Basin

A large multiringed impact structure on the nearside of the Moon, measuring 1123 km at its largest diameter, centered at 32.8 °N, 15.6 °W. It is visible as the lava floodplain known as the Mare Imbrium ('Sea of Showers'). Stratigraphic dating shows the Imbrium Basin to be the second youngest of the Moon's large impact features; had the impact been any greater it would most likely have shattered the Moon completely. The impact took place around 3.85 billion years ago, near the end of the period of intense cratering in the solar system known as late heavy bombardment. Ejecta from the impact covers much of the Moon's nearside. Lava flooding took place over the next 600 million years. Only the outermost ring is fairly well defined by mountain ranges, to the east by Montes Caucasus, to the southeast by Montes Apenninus, and to the south by Montes Carpatus. The Montes Alpes form part of an ill-defined inner ring. To the southwest, Mare Imbrium opens into Oceanus Procellarum. To the northwest, a more recent impact crater has formed Sinus Iridum ('Bay of Rainbows'). Two other prominent craters lie at the eastern edge: Archimedes and Plato. The basaltic lava floodplain of the mare itself is punctuated by Montes Spitzbergen and the isolated peaks Mons Pico and Mons Piton.

Inclination

The angle at which one plane is tilted to another. Taking three examples, first, the inclination of a planetary orbit is normally taken to mean the angle between the plane of the orbit and the plane of the Earth's orbit. The closest and most distant planets have the greatest orbital inclinations—Mercury's orbit is inclined at 7° and Pluto's at 17°. Second, equatorial inclination of a planet is the angle between the plane of its equator and its orbit plane. Third, the inclination of the orbit of an artificial Earth satellite is the angle at which its orbit plane intersects the plane of the equator.

Index Catalog (IC)

A catalog of nebulae and clusters prepared by Danish astronomer J L E Dreyer (1852–1926) as a sequel to his New General Catalog (NGC), which had been published in 1888. The Index Catalogue was published in two parts—'Index Catalog of Nebulae Found in the Years 1888 to 1894 with Notes and Corrections to the New General Catalog' (published in 1895), and 'Second Index Catalog of Nebulae Found in the Years 1895 to 1907; with Notes and Corrections to the New General Catalog and to the Index Catalog for 1888 to 1894' (published in 1908). Objects in this catalog are denoted by the letters 'IC' followed by a number, for example, 'IC 2220'.

A revised edition of the NGC and the two Index Catalogs, edited by R W Sinnott and updated to epoch 2000.0, was published as a single volume in 1988.

Indian Astronomy: History of

From the time of Āryabhaṭa (ca AD 500) there appeared in India a series of Sanskrit treatises on astronomy. Written always in verse, and normally accompanied by prose commentaries, these served to create an Indian tradition of mathematical astronomy which continued into the 18th century. There are as well texts from earlier centuries, grouped under the name *Jyotishavedāṅga*, that is, supposed to belong the latest stage of Vedic literature. These present, somewhat obscurely, a calendrical system governed by a five year cycle.

The general characteristics of the principal treatises, those written by Āryabhaṭa and his successors, seem calculated to induce a certain skepticism on the part of modern readers, who would be inclined to doubt whether any scientific content could be found in these verses. The verses are concise in the extreme, so that in general the prose commentaries are essential for any understanding. The mean motions are expressed by giving the number of revolutions in a huge period of time, typically the *mahāyuga* of 4 320 000 years. There is no tabular presentation, not even in the commentaries, in contrast to Babylonian and Greek texts, so that even the values of the trigonometrical function are given in a verse. The presentation of the mean motions is, as a rule, so closely bound up with the luni-solar calendar, itself dependent on the motions of the Sun and Moon, that it is not clear at first which is being defined. Although the texts show a clear understanding that the Earth is a sphere, and of the prime meridian, together with the need to make corrections for a change of MERIDIAN, that prime meridian is defined as a line passing through 'Lāṅka' (modern Sri Lanka, Ceylon), rather than to the actual site of observation; the commentaries, however, make it clear that Ujjain in Madhya Pradesh was that site. All these difficulties and obscurities have led Europeans to doubt whether the Indians ever observed at all. Modern studies of these texts have produced a wide range of opinions concerning the 'scientific' quality of Indian work, but recently Roger Billard has largely settled the matter by showing that the parameters were closely based on observations; see the section below on modern studies.

The bibliography of the subject is vast, but it seems to be true that the major Sanskrit texts have now been published. There are nevertheless innumerable manuscripts certainly worthy of study; see Pingree (1970 and subsequent volumes) for a survey of the manuscripts and a full bibliography of researches. In recent years important editions and reeditions have been brought out by Indian scholars, notably K S Shukla (Lucknow) and K V Sharma (Madras).

Āryabhaṭa

Āryabhaṭa may fairly be considered as the founder of Indian scientific astronomy. Unusually, the year of his birth, AD 476, is known; however the region of India in which he lived is not known. He is the author of two scientific works, one of which is extant; this has been passed down to us under the name *Āryabhaṭīya*, a name given to the material by later scholars. The other, and earlier, work may be identified as the *Sūrya Siddhānta* as described by Varāhamihira in his *Pañcasiddhāntikā* (ca AD 580). The *Āryabhaṭīya* is known from a number of manuscripts from which good editions and translations have been made; the first European edition was made by H Kern in 1873. Āryabhaṭa's works were referred to as *tantras* in his own life time, *tantra* being a general term for a treatise. Since then the tendency has been to denote the formal canons as *siddhāntas*, and the less formal, intended for easy application with simpler arithmetic, as *karaṇas*.

In the work of Āryabhaṭa one finds, at least in germinal form, a large part of the astronomical science that will develop in India over the centuries that follow, so much does it define the whole paradigm of the subject. The mathematical section is notable for a number of reasons, for an original numerical notation, for the introduction of the sine function essentially as we know it, for the value of $\pi = 3.1416$ and for the procedure of solving indeterminate equations of the form $ax - by = 1$. The astronomical parameters and procedures define completely the mean and true longitudes for the Sun, Moon and planets, as well as various procedures that would be classed as spherical astronomy. It is noteworthy that Āryabhaṭa held that the Earth revolved daily, so accounting for the daily rotation of the heavens; this view was, however, rejected by all later Indian writers.

That the work is indebted in part to Greek astronomy is evident from the use of trigonometry. However, neither the trigonometrical nor the astronomical procedures follow Ptolemaic usage closely. It may be inferred that the transmission of Greek knowledge to India included only material from pre-Ptolemaic stages, even though the transmission must have occurred much later than the time of PTOLEMY (2nd century AD).

The procedures for the computation of the longitudes of Sun, Moon and planets require that first of all the mean longitudes are calculated, always as linear functions of time. The practical epoch employed by Āryabhaṭa is noon 499 March 21 but, for theoretical purposes, he takes a moment 3600 years previous, where the 'year' is that defined by the system. In the *Sūrya Siddhānta* this comes to midnight –3101 February 17/18, while in the *Āryabhaṭīya* it comes to –3101 February 18 at 6 am, because the mean year is slightly shorter in the latter. In either case this defines the epoch of 'Kaliyuga'. All the mean motions are assumed to be zero at that epoch, and the motions are defined by a number of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

revolutions in 4 320 000 years, which is 1 577 917 800 days for the *Sūrya Siddhānta* and 1 577 917 500 days for the *Āryabhaṭīya*. Although the long period 4 320 000 years is found in speculation from much earlier centuries, and which presumably links up with Babylonian schemes, because of its obvious sexagesimal character (20×60^3) (see BABYLONIAN ASTRONOMY), the Kaliyuga as such is not ancient, but originates only with Āryabhaṭa.

An equation (or correction) is added to the mean longitude to give the true longitude. In Indian astronomy such procedures were somewhat simpler than those developed by Ptolemy. For the Sun and Moon, for example, the equation is of the form (in modern notation)

$$\mu(\theta) = \arcsin[\sin(\mu_m)\sin(\theta)]$$

where θ is angle from the apogee to the mean longitude and μ_m is a constant. For the planetary equations a second function is also needed,

$$\sigma(\theta) = \arctan\left(\frac{\sin(\sigma_m)\sin(\theta)}{1+\sin(\sigma_m)\cos(\theta)}\right).$$

These two functions (the so-called *manda* and *śīghra* corrections) were used throughout the Indian procedures for calculating the true longitude. The procedures varied from one author to another, and, indeed, Āryabhaṭa proceeds differently in his two works. In the *Sūrya Siddhānta*, which is simpler in this respect, the true longitude *L* of the outer planets depends on the mean Sun λ_s, the mean planet λ and the planet's apogee Γ; it is fixed after four steps, where α, β and γ are intermediate quantities:

$$\alpha = \Gamma - \tfrac{1}{2}\sigma(\lambda_s - \lambda)$$
$$\beta = \alpha + \tfrac{1}{2}\mu(\lambda - \alpha)$$
$$\gamma = \lambda - \mu(\lambda - \beta)$$
$$L = \gamma + \sigma(\lambda_s - \gamma).$$

The same steps are used for the inner planets, provided only that λ_s and λ are interchanged.

In the *Āryabhaṭīya* the steps differ somewhat, and moreover the 'constants' μ_m, σ_m now vary periodically by small amounts, as expressed by $\mu_1 + \mu_2|\sin\theta|$ and $\sigma_1 + \sigma_2|\sin\theta|$.

It should be noted that all the celestial longitudes are sidereal, not tropical, and are measured from a point on the ecliptic where the equinoctial point was located around the year AD 514. Precession as such plays no role in the *Āryabhatīya*, apparently a deliberate choice, although it occurs in other contemporary work. In any case, with this origin, the precessional correction in Āryabhaṭa's time was very small.

Brahmagupta

After the time of Āryabhaṭa the next figure of note is BRAHMAGUPTA, who flourished during the 7th century. He is noted for two works, the voluminous *Brāhmasphuṭasiddhānta*, and the *Khaṇḍakhādyaka*. The former is a substantial treatise on mathematics as well as astronomy, the latter a short astronomical tract, in which the parameters not only differ from those in the earlier work but agree with the *Sūrya Siddhānta* of Āryabhaṭa. It is interesting that although Āryabhaṭa is heavily criticized in the *Brāhmasphuṭasiddhānta*, the parameters given there are in poor agreement with observations compared with the work of Āryabhaṭa.

Both these works played a significant role in the transmission of Indian astronomy to the Islamic world, where they were known as *Sindhind* and *Arkand*; from the former there was derived, after some modification, the zīj (astronomical handbook) of AL-KHWĀRIZMĪ, ca AD 830 (see also ISLAMIC ASTRONOMY). It is in this period that Indian astronomy was also passed to South East Asia (Burma, Thailand, Cambodia, Indonesia), Nepal, Tibet, Central Asia and China; in South East Asia it was dependent on a source that used the epoch AD 638, an epoch still found in Burma. In fact, the analysis of a Thai calendrical treatise by Giovanni Cassini in 1691 marks the true beginning of the European interest in the subject.

The later centuries

Over the centuries, from the 10th to the 18th, many more treatises and commentaries were written. Under Moghul rule this Sanskrit tradition was deflected from its traditional course by the influence of Islamic work, for example the Persian treatise of ULUGH-BEG. By the early 18th century one curious byproduct of this influence was a Sanskrit translation of Ptolemy's *Almagest*, via a Persian version. At the same time European work became known, especially the Astronomical Tables of Philipp de la Hire (1727), transcribed into Persian as the Zīj-i Muḥammed Shāhī at the court of Jai Singh ca 1730.

Modern study

Once the obscure conventions of the Indian texts are grasped, it is not difficult to make precise calculations of the mean and true positions of the Sun, Moon and planets according to any of these treatises, so that one may compare the results with modern calculations. Comparisons have been made in this way since the early 19th century, most notably by John Bentley (1825) but also by William Dwight Whitney (1860). Bentley's efforts were handicapped both by the shortage of Sanskrit sources then known and by the fact that the parameters of 'modern' astronomy were then inadequate for the purpose. In the end his findings were held up to ridicule by indologists. In recent years, however, this approach has been pursued with singular success by Billard (1971), from whose work it is clearer than anyone might have

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

imagined that the Indian parameters from the time of Āryabhaṭa are based on serious and close, often very exact, observation. Billard's *L'Astronomie indienne* marks a uniquely profound advance in our understanding of the history of Indian astronomy.

Billard studied the mean longitudes provided by the Indian canons. These are sidereal longitudes, deviating therefore from the corresponding modern values by the rate of precession. Taking all of the deviations (Sun, Moon, lunar apogee, lunar node, five planets) one finds that, for most canons, all such deviations agree at only one time, clearly the time when the parameters were fixed to agree with observation. Such a bundle of deviation curves is shown in figure 1, calculated from the *Āryabhaṭīya*. The curves in the bundle diverge widely at other times, because the rates of motion have not been made to fit observations of an earlier date and are indeed controlled to some extent by *a priori* arguments. It is clear that the actual rates of mean motions were not fixed over a long time base but were only accurately fitted to observations in Āryabhaṭa's time. While this is a defect from the astronomical point of view, it also means that the time of that agreement is very securely fixed, in one brief interval near AD 500, when the agreement with observation is excellent. When Billard's determination of the optimum year is extended to find the optimum meridian, we find that that meridian passes through central India, so reinforcing the conclusion that the observations were carried out not only in the time of Āryabhaṭa, but certainly in India, as shown in figure 2 (Mercier 1987). Thus, while his procedures clearly owe something to Greek material, we see that Āryabhaṭa's work is thoroughly Indianized and based on observations made during the lifetime of the author.

Generally speaking the Indian determinations of mean longitudes were not established over a long time base, but there is an outstanding exception in some treatises that appear in the 9th century. These are known partly through the work of Lalla, the *Śishya dhīvṛddhida tantra*. It is not that this work or its author was so outstanding, but it happens that we find here a set of modifications of the received parameters which amount to a set of mean longitudes established accurately over the period AD 500–850 and which so clearly took into account observations made at the earlier date, or if not earlier observations, at least the values of mean longitudes determined at that earlier date. Much later, Acyuta (1550–1620) of Kerala (South India), in his *Sputanirṇayana-tantra*, gave mean longitudes which also agree extremely well together over a very long time base.

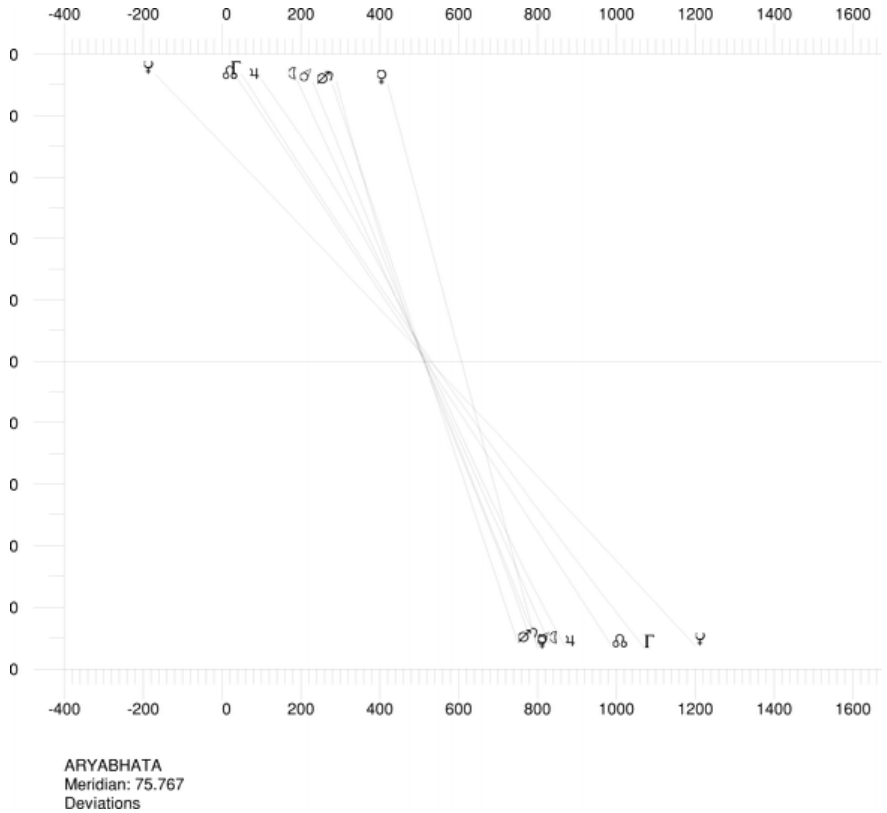

Figure 1. Deviation curves of the mean longitudes according to the *Āryabhaṭīya*. The deviation is the excess over the modern mean longitude.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

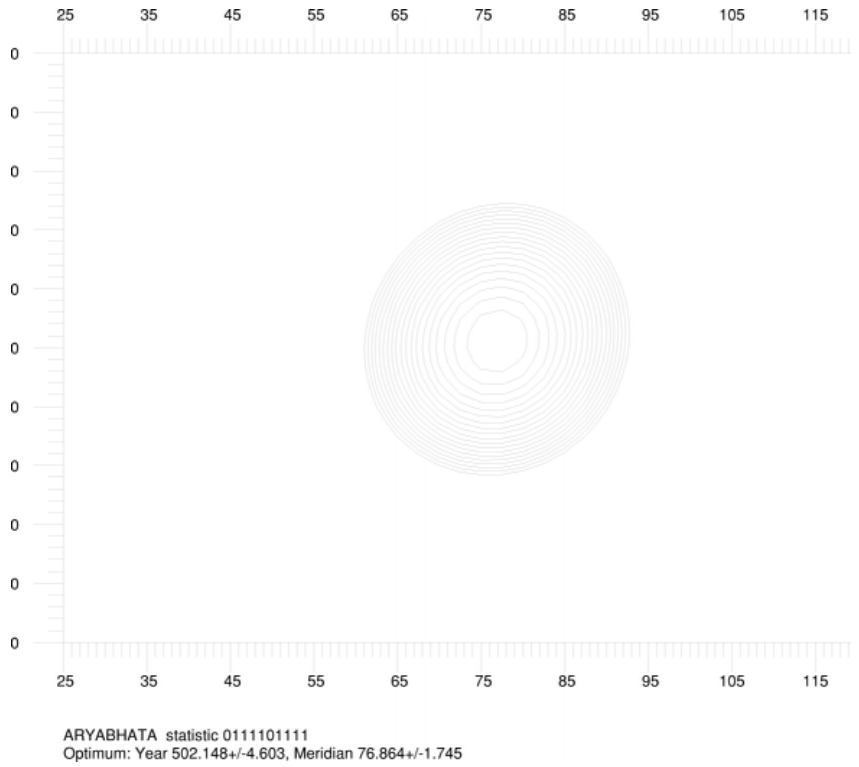

Figure 2. Contour curves showing the optimum meridian and date for the mean longitudes of the *Āryabhaṭīya* for Sun, Moon and all planets except Mercury. The optimum values are 76.86±1.76, 502.15±4.6.

Generally speaking, however, the lesson was not learnt that astronomy is natural history and requires a long time base for the determination of its parameters. There was in Indian astronomy the inbuilt assumption that a certain *a priori* framework based on the long periods, the *yugas*, could always be safely assumed, so that observations made at the time of the composition of the treatise would suffice.

Calendar

The calendar in India is luni-solar, that is it depends on the sequence of lunations, with an intercalated month every second or third year. The lunation is determined by the mean or true conjunction, but never by the visibility of the crescent, in contrast to the Babylonian or Islamic calendar (see CALENDAR IN THE MIDDLE EAST AND EUROPE).

At some time in the period following Āryabhaṭa the calendar came to be calculated according to one of the many treatises on astronomy. This had the effect of introducing certain formalities into the dating formula, in particular the 'lunar day' (*tithi*; see technical terms), in place of the ordinary civil day. In other respects the dating formula remained similar to that found in earlier periods.

There is a wealth of inscriptions in India, going back at least to the time of Aśoka (3rd century BC), and many are dated. Manuscripts also carry dates in their colophons. This means that there is much material from which to determine the application of the various astronomical procedures. Conversely, the historian calls upon expert understanding of the astronomical reckoning in order to interpret the date. Although a number of differing treatises have been used in practice to fix dates, the results rarely differ, and then by at most one day, or rather *tithi*. The era used in the date must also be established, and there are indeed many found in India. The era used in astronomy is the Śaka era, reckoned from AD 78, while the Vikrama era, from 57 BC, is widely used elsewhere.

The calendrical scheme

The calendrical scheme may be briefly sketched. The names of the months are as follows.

Caitra	Āśvina
Vaiśākha	Kārttika
Jyeshṭa	Mārgaśirsha
Āshāḍha	Pausha
Śrāvana	Māgha
Bhādrapada	Phālguna

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

These names are taken from the names of the 27 *nakshatras* (see the technical terms). Each month begins at sunrise following the moment of lunation. The Indian names for the zodiacal signs are given in the following table, together with the corresponding Western names. The Indian names are essentially translations of the Western names, so that, Mesha, for example, means 'ram'.

Aries	Mesha
Taurus	Vṛshabha
Gemini	Mithuna
Cancer	Karka
Leo	Siṃha
Virgo	Kanyā
Libra	Tulā
Scorpio	Vṛścika
Sagittarius	Dhanus
Capricorn	Makara
Aquarius	Kumbha
Pisces	Mīna

The coordination of the month and zodiacal names is so arranged that the new Moon at which Caitra begins is the last one before the Sun enters Mesha. The same monthly names are used, in addition, to specify 12 solar months. In this system, Solar Caitra begins when the Sun enters Mīna, and so on. In some inscriptions the date is given in terms of the solar months, rather than lunar months.

As in any luni-solar calendar there are intercalary months, but the Indian system is quite complex, and is such that any month might be repeated in order to keep the lunar months in step with the seasons. It may happen that the Sun does not enter a new sign from one lunation to the next, in which case the month of that name is repeated. In the same way it may enter two successive signs between two lunations, in which case the month name corresponding to the second sign is omitted. If mean lunations are used it is always the case that the interval of time between successive entries into signs is less than the mean interval between lunations, so that there are no omitted months. In either system there are always repeated months.

If the year begins in the spring the new year begins with the month Caitra, or if that month is omitted, with the month Vaiśākha. If the year begins in the autumn the new year begins with the month Kārttika, or if that month is omitted, with the month Mārgaśirsha.

Indian dates do not refer to the ordinary civil day, but to the so-called *tithi*, the lunar day. This is defined as the interval of time in which the luni-solar elongation increases by 12º. If mean lunations are used, this interval is 1/30 of the mean synodic month. The precise length of the mean *tithi* depends on the canon, but it is very nearly 0.984 of the ordinary civil day. The first *tithi* of the month begins at the moment of lunation (true or mean).

The *tithis* are counted from 1 to 15, in the first or 'bright' fortnight, starting with the new Moon, and from 1 to 15 again in the second or 'dark' fortnight, starting with the full Moon. The *tithi* in the 'bright' fortnight is marked *sudi*, an acronym for *shukla paksha dina*, and the *tithi* in the 'dark' fortnight is marked *badi*, an acronym for *bahula paksha dina*. In most cases only one sunrise occurs during the interval of the *tithi*, and that *tithi* occurs, and once only, in the sequence. However, in other cases, a *tithi* may be omitted or repeated. If it is omitted, it is because it begins after one sunrise, and ends before the next. If it is repeated, it is because it begins before one sunrise and ends after the next.

The course of the Moon is plotted against a division of the sky into 27 *nakshatras*, so-called 'lunar mansions'. These are each related to certain stars, and if their positions were strictly recognized the *nakshatras* would have varying widths. It is more common to assume a constant width of 13º 20' for each.

Almanacs

The Indian ALMANAC in the form of the *pañcāṅga* is widely available at a popular level. The almanacs are written in one of the Indian languages, Hindi, Gujarati, etc, not in English. These are popular works, intended essentially for the astrology market, which flourishes in India. Nevertheless, they are no less interesting to the historian of astronomy, continuing as they do the tradition of the medieval astronomical handbook, the zīj of Arabic–Persian tradition, itself based on the *Handy Tables* of Ptolemy. The *pañcāṅga*, as the name indicates, consists of five elements, namely *tithi*, *vāra*, *nakshatra*, *yoga*, *karaṇa* (see the technical terms). These concern only the Sun and Moon, and are the principal elements of an Indian date. Typically the almanac will go further to give the actual positions of the Sun, Moon and planets (always sidereal positions), and much besides, including a profusion of articles, many concerning astrology. It is in some ways a popular and accessible equivalent of the Astronomical Ephemeris, in contrast to the official Indian equivalent, the *Indian Ephemeris and Nautical Almanac*.

It is likely that, at the present time, most if not all of these calendars are founded on modern elements as represented in the *Indian Ephemeris*, which in turn agrees entirely with its Western counterparts, both in style and content. Indeed the positions of Sun, Moon and planets are in some almanacs not given for the Indian central meridian (82º 40' E of Greenwich) but for the Greenwich meridian.

The more ambitious of these almanacs give far more than the five basic elements and provide almost as much as the official Nautical Almanac, but in a somewhat more accessible form. These works suffer from the absence of any full acknowledgment of the methods of calculation,

or their source. However, the survey carried out for the Calendar Reform Committee (1955) included a survey of more than 50 of these almanacs, and the results showed whether traditional or modern sources of parameters had been employed, along with other technical details, including the *ayanāṃśa*.

Technical terms

It is convenient to collect here a number of the technical terms used in the Indian almanacs.

ayanāṃśa. Effectively a measure of precession, applied to the sidereal longitudes computed from the canon.
karaṇa. A sort of half-*tithi*, the interval during which the luni-solar elongation increases by 6º.
nakshatra. One of the 27 divisions of the ecliptic, named after the 27 (or 28) small constellations known collectively as the *nakshatras*.
pañcāṅga. 'Five elements', namely *tithi*, *vāra*, *nakshatra*, *yoga*, *karaṇa*.
tithi. Interval of time counted from luni-solar conjunction, representing increments of 12º in the elongation. Mean and true *tithis* are recognized, according to whether the positions of the Sun and Moon are mean or true.
yoga. The interval during which the sum of the solar and lunar positions increase by 12º.
vāra. Weekday.

Indus

(the Indian—usually represented as a Native American; abbrev. Ind., gen. Indi; area 294 sq. deg.) A southern constellation which lies between Telescopium and Grus, and culminates at midnight in mid-August. It was first shown on Petrus Plancius' celestial globe of *c.* 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, the brightest stars in Indus are α Indi, magnitude 3.1, and β Indi, magnitude 3.7. There are no other stars brighter than fourth magnitude. ε Indi, magnitude 4.7, distance 11.8 light-years, has a proper motion of 3.96″ per year, which will bring it close to the south celestial pole in about 50 000 years. Interesting objects include θ Indi, a binary star with bluish-white (A5) and yellow (G0) components, magnitudes 4.5 and 7.2, separation 6.7″, and NGC 7049, an eleventh-magnitude spiral galaxy.

Inertia

The resistance of a massive body to any change in its velocity. Any body will continue in a state of rest or of uniform straight-line motion unless acted upon by a force. Thus a spacecraft, when its rocket motors are switched off, follows a ballistic trajectory because of its inertia. In Newton's second law of motion, the relationship between acceleration, a, of a body and the applied force, F, is $F = ma$, where m is the inertial mass of the body. As far as can be determined, the inertial mass of a body is exactly equal to its gravitational mass, which determines its gravitational attraction. This is called the Equivalence Principle. There does not seem to be any *a priori* reason why these two masses should be exactly equal, and there is still considerable debate on the question of the nature of inertia.

Inferior Planets

A collective term for the major planets Mercury and Venus, whose orbits lie within that of the Earth, as opposed to the superior planets, those major planets whose orbits lie outside the Earth's.

Compare: inner planets.

Inflation

According to inflationary theory, there was a stage of exponentially rapid expansion of the early universe. The existence of this stage resolves many long-standing problems of the BIG BANG THEORY and changes our understanding of the origin of the universe and of its global structure.

Inflation and the big bang theory

Inflationary cosmology describes the very early stages of the evolution of the universe and its structure at extremely large distances from us. For many years, cosmologists believed that the universe from the very beginning looked like an expanding ball of fire. This explosive beginning of the universe was called the big bang. In the end of the 1970s a different scenario for the universe's evolution was proposed. According to this scenario, the universe at the very early stages of its evolution came through the stage of inflation, an exponentially rapid expansion in a kind of unstable vacuum-like state (a state with large energy density, but without elementary particles). This stage could be very short, but the universe within this time became exponentially large. At the end of inflation the vacuum-like state decayed, the universe became hot and its subsequent evolution could be described by the standard big bang theory (see also UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION, UNIVERSE: THERMAL HISTORY).

The existence of the inflationary stage is necessary to resolve many difficult problems which arise when one tries to unify the modern theory of elementary particles and the standard big bang theory. The standard big bang theory asserts that the universe was born at some moment $t = 0$ about 15 billion years ago, in a state of extremely high temperature T and density ρ (cosmological singularity). It is usually assumed that the standard description of the universe in terms of space and time becomes possible at the Planck time $t \sim 10^{-43}$ s after the singularity, when its density drops below the so-called Planck density $\rho_p \sim 10^{94}$ g cm^{-3} (see UNIVERSE: DENSITY). (At greater density, quantum fluctuations of space–time are so large that an alternative description of space-time is required.) The temperature of the expanding universe gradually decreased, as the reciprocal of its size, and finally the universe evolved into the relatively cold universe where we live now. Remnants of this primordial cosmic fire still surround us in the form of the microwave background radiation with a temperature of 2.7 K.

This theory was extremely successful in explaining various features of our world. However, in combination with the modern theory of elementary particles, it predicts the existence of a large amount of superheavy stable particles carrying magnetic charge: magnetic monopoles. These objects have a typical mass 10^{16} times that of the proton. According to the standard big bang theory, monopoles should appear at the very early stages of the evolution of the universe, and they should now be as abundant as protons. In that case the mean density of matter in the universe would be about 15 orders of magnitude higher than its present value of about 10^{-29} g cm^{-3}.

In addition to this problem, the standard big bang theory was unable to answer many other questions. For example, the universe is closed if $\Omega = \rho/\rho_c > 1$, it is flat if $\Omega = 1$ and it is open if $\Omega < 1$. Here ρ is the density of the universe, ρ_c is the critical density, which at the present epoch is of the order 10^{-29} g cm^{-3}. The value of the parameter Ω changes in an expanding universe. Observational data suggest that now $0.3 < \Omega < 1.2$, which does not seem unnatural. However, according to the big bang theory, this requires that at the Planck time the value of Ω should coincide with 1 with an accuracy of 10^{-60}. A slightly higher value of Ω would lead to a closed universe which would immediately collapse; a slightly smaller value of Ω would lead to an open universe, which at present would be practically empty. The need for this incredible fine tuning of initial conditions in the standard big bang theory is the essence of the flatness problem.

One may also wonder, where did the universe come from? How could it happen that its different, causally disconnected parts could begin their expansion simultaneously? Why it is so big, homogeneous and isotropic? If it must be homogeneous for whatever reason, then what is the origin of galaxies? Why is our space three-dimensional? Is it possible that our universe could be created differently?

All these problems are extremely difficult, and some of them sound almost metaphysical. That is why it is so encouraging that most of the problems mentioned above can be resolved in the context of one simple scenario of the evolution of the universe—the inflationary universe scenario.

New theories of elementary particles and the notion of a scalar field

Inflationary theory became possible owing to the rapid progress of the theory of elementary particles during the last two decades, after physicists have found a way to unify weak, strong and electromagnetic interactions (see STANDARD MODEL OF PARTICLE PHYSICS).

It is well known that electrically charged particles interact with each other by creating an electromagnetic field around them. Small excitations of this field are called photons. Photons do not have any mass, which is the main reason why electrically charged particles can easily interact with each other at a very large distance. Weak and strong interactions are mediated by similar particles. For example, weak interactions are mediated by particles called W and Z. However, whereas photons are massless particles, the particles W and Z are extremely heavy; it is very difficult to produce them. That is why weak interactions are so weak. In order to obtain a unified description of weak and electromagnetic interactions despite the obvious difference in properties of photons and the W and Z particles, physicists introduced scalar fields ϕ, which will play the central role in our discussion.

The closest analog of a scalar field is the electrostatic potential Φ. Electric and magnetic fields appear only if this potential is inhomogeneous or if it changes in time. If the whole universe were to have the same electrostatic potential, then nobody would notice it; it would be just another vacuum state. Similarly, a constant scalar field ϕ looks like a vacuum state; we do not see it even if we are surrounded by it.

The main difference is that the constant electrostatic potential Φ does not have its own energy, whereas the scalar field ϕ may have potential energy density $V(\phi)$. If $V(\phi)$ has one minimum at $\phi = \phi_0$, then the whole universe eventually becomes filled by the field ϕ_0. This field is invisible, but, if it interacts with the W and Z particles, they become heavy. Meanwhile, if photons do not interact with the scalar field, they remain light. Therefore we may begin with a theory in which all particles initially are light and there is no fundamental difference between weak and electromagnetic interactions. This difference appears later, when the universe becomes filled by the scalar field ϕ. At this moment the symmetry between different types of fundamental interactions becomes broken. This is the basic idea of all unified theories of weak, strong and electromagnetic interactions. A scalar field ϕ of a similar type is the main ingredient of inflationary theory.

Development of inflationary theory

According to the big bang theory, the rate of expansion of the universe given by the HUBBLE 'CONSTANT' $H(t)$ is (approximately) proportional to the square root of its density. If the universe is filled by ordinary matter, then its density rapidly decreases as the universe expands. Therefore expansion of the universe rapidly slows down as its density decreases. This rapid decrease of the rate of the universe's expansion is the main reason for all our problems with the standard big bang theory. However, because of the equivalence of mass and energy established by Einstein ($E = mc^2$), the potential energy density $V(\phi)$ of the scalar field ϕ also contributes to the rate of expansion of the universe. In certain cases the energy density $V(\phi)$ decreases much more slowly than the density of ordinary matter. This may lead to the existence of a stage of extremely rapid expansion (inflation) of the universe.

The first version of inflationary theory was proposed in 1979 by Alexei Starobinsky of the Landau Institute, Moscow. Starobinsky's model created a sensation among Russian astrophysicists, and for two years it remained the main topic of discussion at all conferences on cosmology in the Soviet Union. However, his model was rather complicated, being based on the theory of anomalies in QUANTUM GRAVITY; it was not well known outside of Russia.

The crucial step in the development of inflationary theory was made in 1981 by Alan Guth of MIT. He suggested that the hot universe at some intermediate stage could expand exponentially, being in an unstable supercooled state called the 'false vacuum'. He called this stage of exponential expansion 'inflation'. The main idea of his model was based on the theory of cosmological phase transitions with supercooling, which was developed in the mid-1970s by David Kirzhnits and Andrei Linde at the Lebedev Institute, Moscow. This scenario was so attractive that even now many people associate inflation with expansion in a false vacuum. Unfortunately, as Guth has found himself, the universe after inflation in his scenario becomes extremely inhomogeneous. After a year of investigation, Guth, in his paper with Eric Weinberg of Columbia University, concluded that his model could not be improved.

In 1982 Linde introduced the so-called new inflationary universe scenario, which later was also discovered by Andreas Albrecht and Paul Steinhardt at the University of Pennsylvania. Inflation in this scenario occurs not only in the false vacuum $\phi = 0$ but also when the scalar field ϕ begins slowly moving towards the minimum of $V(\phi)$. This scenario was free of the main problems of the model suggested by Guth, but it was rather complicated. It assumed that the universe from the very beginning was extremely large and hot, that it was in a state of thermal equilibrium although the field ϕ was practically decoupled from all other particles. It also required the potential $V(\phi)$ to have a very specific, fine-tuned form. No realistic versions of this scenario have been proposed so far.

Finally, in 1983 Linde has found that inflation can naturally occur in many theories of elementary particles. There is no need for quantum gravity effects, phase transitions and supercooling. There is no need to assume that the whole universe was created at the same moment, that it was in a state of thermal equilibrium and that the scalar field from the very beginning was at the minimum of its potential energy density. One should consider all possible chaotic distributions of the scalar field in the early universe, and then check whether some of them lead to inflation. Those places where inflation does not occur remain small, whereas those domains where inflation takes place become exponentially large and give the main contribution to the total volume of the universe. This scenario was called 'chaotic inflation'. Its simplest version was described in the previous section. In the context of this scenario inflation is not an exotic phenomenon invoked by theorists for solving their problems. It is a very general regime which occurs in a wide class of theories including many models with polynomial and exponential potentials $V(\phi)$.

Chaotic inflation

To explain the basic idea of chaotic inflation, let us consider the simplest model of a scalar field ϕ with a mass m and with the potential energy density $V(\phi) = (m^2/2)\phi^2$ (figure 1). Since this function has a minimum at $\phi = 0$, one may expect that the scalar field ϕ should oscillate near this minimum. This is indeed the case if the universe does not expand. However, one can show that in a rapidly expanding universe the scalar field moves down very slowly, as a ball in a viscous liquid, viscosity being proportional to the speed of expansion.

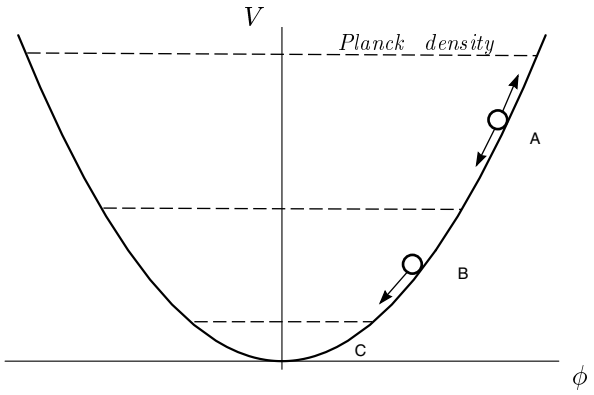

Figure 1. Motion of the scalar field in the theory with $V(\phi) = (m^2/2)\phi^2$. Several different regimes are possible, depending on the value of the field ϕ. If the potential energy density of the field is greater than the Planck density 10^{94} g cm^{-3}, quantum fluctuations of space–time are so strong that one cannot describe it in usual terms. Such a state is often called space-time foam. At a somewhat smaller energy density (region A) quantum fluctuations of space–time are small, but quantum fluctuations of the scalar field ϕ may be large. Jumps of the scalar field due to quantum fluctuations lead to a process of eternal self-reproduction of inflationary universe which we are going to discuss later. At even smaller values of $V(\phi)$ (region B) fluctuations of the field ϕ are small; it slowly moves down as a ball in a viscous liquid. Inflation occurs in both the region A and region B. Finally, near the minimum of $V(\phi)$ (region C) the scalar field rapidly oscillates, creates pairs of elementary particles, and the universe becomes hot.

There are two equations which describe the evolution of a homogeneous scalar field in our model:

$$H^2 + \frac{k}{a^2} = \frac{4\pi G}{3}(\dot\phi^2 + m^2\phi^2)$$
$$\ddot\phi + 3H\dot\phi = -m^2\phi.$$

Here $H = \dot a/a$ is the Hubble parameter in the universe with a scale factor $a(t)$, $k = -1, 0, 1$ for an open, flat or closed universe respectively, G is the gravitational constant. The first of these two equations is the Einstein equation for a homogeneous universe containing a scalar field ϕ with energy density $\rho = \dot\phi^2/2 + m^2\phi^2/2$. The second equation is the standard Klein–Gordon equation for a homogeneous scalar field. The only difference (but a very important one) is the presence of the term $3H\dot\phi$, which appears owing to the expansion of the universe. This equation is similar to the equation of motion for a harmonic oscillator, where instead of $x(t)$ we have $\phi(t)$, with a friction term $3H\dot\phi$.

If the scalar field ϕ initially was large, the Hubble parameter H was large too, according to the first equation. This means that the friction term $3H\dot\phi$ in the second equation was very large, and therefore the scalar field was moving very slowly, as a ball in a viscous liquid. Therefore at this stage the energy density of the scalar field, unlike the density of ordinary matter, remained almost constant, and expansion of the universe continued with a much greater speed than in the old cosmological theory. Because of the rapid growth of the scale of the universe and the slow motion of the field ϕ, soon after the beginning of this regime one has $\ddot\phi \ll 3H\dot\phi$, $H^2 \gg k/a^2$, $\dot\phi^2 \ll m^2\phi^2$, so the system of equations can be simplified:

$$\frac{\dot a}{a} = 2m\phi\left(\frac{\pi G}{3}\right)^{1/2} \qquad 3\frac{\dot a}{a}\dot\phi = -m^2\phi. \tag{1}$$

The first equation shows that if the field ϕ changes very slowly, then the size of the universe grows approximately as e^{Ht}, where $H = (8\pi G V(\phi)/3)^{1/2} = 2m\phi(\pi G/3)^{1/2}$.

This stage of exponentially rapid expansion of the universe is called inflation. In realistic versions of inflationary theory its duration could be as short as 10^{-35} s. When the field ϕ becomes sufficiently small, viscosity becomes small, inflation ends and the scalar field ϕ begins to oscillate near the minimum of $V(\phi)$. As any rapidly oscillating classical field, it loses its energy by creating pairs of elementary particles. These particles interact with each other and come to a state of thermal equilibrium with some temperature T. From this time on, the corresponding part of the universe can be described by the standard hot universe theory.

The main difference between inflationary theory and the old cosmology becomes clear when one calculates the size of a typical inflationary domain at the end of inflation. Investigation of this question shows that even if the size of inflationary universe at the beginning of inflation in our model was as small as the Plank size $l_{\rm P} \sim 10^{-33}$ cm, after 10^{-35} s of inflation the universe acquires a huge size of $l \sim 10^{10^{12}}$ cm. These numbers are model dependent, but in all realistic models this size appears to be many orders of magnitude greater than the size of the part of the universe which we can see now, $l \sim 10^{28}$ cm. This immediately solves most of the problems of the old cosmological theory.

Our universe is so homogeneous because all inhomogeneities were stretched $10^{10^{12}}$ times. The density of primordial monopoles and other undesirable 'defects' becomes exponentially diluted by inflation. The universe becomes enormously large. Even if it was a closed universe of a size $\sim 10^{-33}$ cm, after inflation the distance between its 'south' and 'north' poles becomes many orders of magnitude greater than 10^{28} cm. We see only a tiny part of the huge cosmic balloon. That is why the universe looks so flat. That is why we do not need expansion of the universe to begin simultaneously in many different causally disconnected domains of a Planck size.

If one considers a universe which initially consisted of many domains with chaotically distributed scalar field ϕ (or if one considers different universes with different values of the field), then domains in which the scalar field was too small never inflated. The main contribution to the total volume of the universe will be given by those domains which originally contained a large scalar field ϕ. Inflation of such domains creates huge homogeneous islands out of initial chaos. Each inflationary domain in this scenario is much greater than the size of the observable

part of the universe. The properties of space inside each such domain after inflation practically do not depend on initial conditions at the beginning of inflation.

Quantum fluctuations as a source for galaxy formation

Solving many difficult cosmological problems simultaneously by a rapid stretching of the universe may seem too good to be true. Indeed, if all inhomogeneities were stretched away, there will be no inhomogeneities left, and these are necessary for the creation of galaxies (see GALAXY FORMATION). Fortunately, while removing previously existing inhomogeneities, inflation at the same time created new ones. The basic mechanism can be understood as follows.

According to quantum field theory, empty space is not entirely empty. It is filled with quantum fluctuations of all types of physical fields. These fluctuations can be regarded as waves of physical fields with all possible wavelengths. If the values of these fields, averaged over some macroscopically large time, vanish, then the space filled with these fields seems to us empty and can be called the vacuum.

In the inflationary universe the vacuum structure is more complicated. Those waves which have very short wavelength 'do not know' that the universe is curved; they move in all directions with a speed approaching the speed of light. However, inflation very rapidly stretches these waves. Once their wavelengths become sufficiently large, these waves begin feeling that the universe is curved. At this moment they stop moving because of the effective viscosity of the expanding universe with respect to the scalar field.

The first quantum fluctuations to freeze are those with large wavelengths. The amplitude of the frozen waves does not change later, whereas their wavelengths grow exponentially. In the course of expansion of the universe newer and newer fluctuations become stretched and freeze on the top of each other. At that stage one cannot call these waves 'quantum fluctuations' anymore. Most of them have exponentially large wavelengths. These waves do not move and do not disappear on being averaged over large periods of time. What we obtain is an inhomogeneous distribution of the classical scalar field ϕ which does not oscillate. Perturbations of the scalar field create Gaussian adiabatic perturbations of the metric (density perturbations). It is these perturbations that are responsible for the subsequent appearance of galaxies and formation of the large-scale structure of the universe.

Note that the amplitude of inflationary perturbations depends on the Hubble parameter H, which changes only very slowly during inflation. At the same time, the wavelength of the perturbations grows exponentially. As a result, the amplitude of the density perturbations is nearly scale independent; they have flat spectrum. The fact that inflation produces adiabatic Gaussian perturbations with a nearly flat spectrum practically does not depend on the choice of the inflationary potential $V(\phi)$, even though the amplitude of the perturbations does depend on $V(\phi)$. In addition to adiabatic perturbations, inflation produces gravitational waves, which also have a flat spectrum.

Eternal inflation

The possibility that galaxies appear as a result of quantum fluctuations may seem very unusual. However, a further pursuit of this idea has led to an even less expected conclusion: quantum fluctuations may lead to an eternal process of self-reproduction of the universe. This effect is rather general, but it looks especially surprising and leads to most dramatic consequences in the context of the chaotic inflation scenario.

As we already mentioned, one can visualize quantum fluctuations of the scalar field in inflationary universe as waves, which move in all possible directions and then freeze on the top of each other. Each freezing wave slightly increased the value of the scalar field in some parts of the universe and slightly decreased this field in other parts of the universe.

Consider those rare parts of the universe where these freezing waves always increased the value of the scalar field ϕ, persistently pushing the scalar field uphill, to the larger values of its potential energy $V(\phi)$. This is an unusual and obviously improbable regime. Indeed, the probability that the field ϕ will make one jump up (instead of jump down) is equal to $1/2$ and the probability that the next time it also jumps up is also $1/2$, so that the probability that the field ϕ without any special reason will make N consecutive jumps in the same direction is extremely small; it will be proportional to $1/2^N$.

Normally one neglects such fluctuations. However, in inflationary cosmology they can be extremely important. Indeed, those rare domains of the universe where the field jumps high enough begin exponentially expanding with ever-increasing speed. Remember that the inflationary universe expands as e^{Ht}, where the Hubble constant is proportional to the square root of the energy density of the field ϕ. In the simple model with $V(\phi) = (m^2/2)\phi^2$ the Hubble constant H will be simply proportional to ϕ. Thus, the higher the field ϕ jumps, the faster the universe expands. Very soon those rare domains, where the field ϕ persistently climbs up the wall, will acquire a much greater volume than those domains which keep sliding to the minimum of $V(\phi)$ in accordance with the laws of classical physics.

This implies that, if the universe contains at least one inflationary domain of a sufficiently large size, it begins unceasingly producing newer and new inflationary domains. Inflation at each particular point may stop very quickly, but there will be many other places which will continue expanding exponentially. The total volume of all inflationary domains will grow without end. This picture differs considerably from the standard big bang cosmology which assumed that our universe is similar to one huge homogeneous expanding ball. According to the new theory, our universe is not a ball but a fractal,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

which looks like a tree consisting of an infinite number of inflationary balloons producing new balloons.

In this scenario the universe as a whole is immortal. Each particular part of the universe may appear from a singularity somewhere in the past, and it may end up in a singularity somewhere in the future. However, there is no end to the evolution of the whole universe. The situation with the beginning is less certain. It is most probable that each part of the inflationary universe has originated from some singularity in the past. However, at present we do not have any proof that all parts of the universe were created simultaneously in a general cosmological singularity, before which there was no space and time at all. Moreover, the total number of inflationary bubbles on our 'cosmic tree' exponentially grows in time. Therefore most of the bubbles (including our own part of the universe) grow indefinitely far away from the root of this tree. This does not necessarily eliminate the big bang, but it removes the possible beginning of the whole universe to the indefinite past.

Until now we have considered the simplest inflationary model with only one scalar field ϕ. However, in realistic models of elementary particles there are many different scalar fields. For example, in the unified theories of weak and electromagnetic interactions there exist at least two other scalar fields, Φ and H. In some versions of these theories the potential energy density of these fields has about a dozen different minima of the same depth. During inflation these fields, just as the field ϕ, jump in all possible directions owing to quantum fluctuations. After inflation they fall down to different minima of their energy density in different exponentially large parts of the universe. Scalar fields change properties of elementary particles and the laws of their interaction. This means that after inflation the universe becomes divided into exponentially large domains with different laws of low-energy physics.

Note that, if fluctuations are not too strong, scalar fields cannot jump from one minimum of their energy density to another. In this case the new parts of the inflationary universe remember the 'genetic code' of their parents. However, if fluctuations are sufficiently large, mutations occur. In some inflationary models quantum fluctuations become so strong that even the effective number of dimensions of space and time can change. According to these models, we find ourselves inside a four-dimensional domain with our kind of physical laws not because domains with different dimensionality and with different particle properties are impossible or improbable, but simply because our kind of life cannot exist in other domains.

Inflation, observational data and particle physics

In addition to explaining many features of our world, inflationary theory makes several important predictions. First of all, most of the inflationary models predict that the universe should be extremely flat, $\Omega = 1 \pm 10^{-4}$ [1]. It is possible to have inflationary models with $\Omega < 1$ (open inflation). So far all models of this type are much more complicated than the models which lead to $\Omega = 1$.

Also, as we already mentioned, inflation generates Gaussian adiabatic perturbations of metric with a nearly scale-independent (flat) spectrum. This is one of the most important and robust predictions of inflationary cosmology that can be experimentally tested. We are unaware of any non-inflationary mechanism that would produce such perturbations.

Flatness of the universe can be experimentally verified, since the density of a flat universe is related in a very simple way to the speed of its expansion given by the Hubble constant. So far observational data are consistent with the simplest possibility $\Omega = 1$. If it happens that the total energy density is smaller than ρ_c, so that the universe is open, it will be necessary to make substantial adjustments to inflationary theory and consider models of open inflation.

Properties of density perturbations produced during inflation can be tested not only by looking at the distribution of matter in the universe. These perturbations make their imprint on the COSMIC MICROWAVE BACKGROUND radiation. They make the temperature of this radiation slightly different in different places in the sky. This is exactly what was found by the Cosmic Background Explorer (COBE) and later confirmed by several other groups of observers.

A new generation of satellites measuring the anisotropy of the microwave background radiation will bring us much more detailed information about the spectrum of perturbations of the metric in the early universe. This information, combined with independent investigation of Ω by other methods, will make it possible to perform a thorough test of various versions of inflationary theory. It may rule out many particular versions of inflationary theory. However, even though each particular version of inflationary theory can be tested, it may be difficult or even impossible to rule out the main idea of inflationary cosmology. For example, as we already mentioned, if observations show that the universe is not flat but open, we will need to consider more complicated versions of inflationary theory. However, it is important that these versions do exist. Meanwhile, at present we do not have any non-inflationary theory of an open universe which would explain why the universe is so homogeneous and predict the small inhomogeneities ('ripples in space') discovered by COBE.

It is too early to claim that the recent observational data have confirmed inflationary theory, but it is certainly true that these results already at their level of accuracy could definitively disprove most of the inflationary models, and this did not happen. Recent observational data give certain evidence in favor of the simplest

[1] Note that, from the point of view of the geometry of the universe, the flatness condition $\Omega = 1$ takes into account the contributions to ρ from all sources, including vacuum energy, or cosmological constant. However, astronomers often exclude the contribution to Ω from the vacuum energy, which sometimes leads to terminological misunderstandings.

versions of inflationary theory predicting a flat universe with a flat spectrum of Gaussian adiabatic perturbations. Meanwhile, during the last few years the observational data practically ruled out the only alternative mechanism of formation of the large-scale structure of the universe, based on the theory of topological defects. Note also that the theory of topological defects did not address any other problems of the standard big bang theory that have been solved by inflation. Thus, although we still do not know whether inflationary theory is true, perhaps it is fair to say that it is the only internally consistent cosmological theory that is at present available.

Inflationary theory is changing together with the rapid development of elementary particle theory. The greatest challenge is to obtain a natural realization of the inflationary universe scenario in the context of supergravity, string theory or M-theory. This appears to be a very difficult task. In order to accomplish it, many different inflationary models have been suggested, some of which are based on investigation of more complicated theories with several different scalar fields. The list of new models includes 'extended inflation', 'natural inflation', 'topological inflation,' 'hybrid inflation,' etc. Most of these models are based on the same physical principles as the simplest chaotic inflation model discussed above, but each of them has its own unique features which can be experimentally tested.

Conclusion

For many centuries scientists believed that the universe is static. Later, they learned that the universe expands. This was a psychological shock, which provoked many attempts to restore stationarity either by modifying the Einstein equations or by invoking permanent matter creation in a steady-state universe. Eventually all these attempts failed. Discovery of the cosmic microwave background radiation and successful prediction of abundances of hydrogen, helium and other elements in the universe confirmed the big bang theory. Finally, the inflationary scenario appeared, which solved many of the intrinsic problems of the big bang cosmology and apparently removed the last doubts concerning its validity.

However, the development of the inflationary theory is gradually giving rise to a completely new cosmological paradigm, which is considerably different from the old big bang theory and even from the first versions of inflationary cosmology. The universe appears to be both chaotic and homogeneous, expanding and stationary. It may consist of many exponentially large domains with different laws of low-energy physics and perhaps even with different dimensionality. Our cosmic home grows, fluctuates and eternally reproduces itself in all its possible forms, as if adjusting itself for all possible types of life which it can support. Some parts of the new theory, it is hoped, will stay with us for years to come, some others may be considerably modified in the nearby future. However, it seems that the last 20 yr of development of cosmology have already changed in an irreversible way our understanding of the structure and the fate of our universe and of our own place in the world.

Inflationary Universe

A modification to the standard Big Bang model that incorporates a period of exponential (accelerating) expansion, called 'inflation' into the early evolution of the universe. In a typical inflationary scenario, the exponential expansion would have started about 10^{-34} s after the beginning of time and would have ended when the universe was, say, a hundred times older (i.e. after about 10^{-32} s). During this time interval (the 'inflationary epoch'), all distances in the universe would have increased by a factor of about 10^{50}. An inflationary factor of 10^{50} corresponds to a region of space 10^{-34} light-seconds in radius and would expand to a radius of about 10^{16} light-seconds (about 300 million light years). Although this appears to imply expansion 'faster than light', because inflation involves the expansion of space, rather than the motion of particles through space, it does not contradict Einstein's assertion that nothing can exceed the velocity of light.

According to grand unified theories of elementary particles and forces, inflation was driven by a change that occurred, about 10^{-34} s after the beginning of time, when the grand unified force separated into the strong and electroweak forces and immense quantities of energy were released that previously had been stored in the vacuum of spacetime. This 'phase change' in the state of the universe has been likened to the change that occurs when water turns to ice and heat ('latent heat') is released.

The inflationary hypothesis was introduced in 1981 by American mathematical physicist Alan Guth, in order to tackle a number of outstanding issues in cosmology, including the 'flatness' problem and the 'horizon problem'. The flatness problem arises from the fact that observations indicate that the mean density of the universe is within a factor of ten of the critical density, the density of a so-called 'flat' universe (one in which the net overall curvature of space is zero). Standard Big Bang models imply that had the mean density differed even microscopically from the critical value in the first instants of the history of the universe, it would differ from the critical value by a huge factor now. The horizon problem relates to the question of how the universe on the large scale came to be so homogeneous and isotropic (the same everywhere and in all directions). For example, when we look at the microwave background in opposite regions of the sky, that radiation has been traveling through space for virtually the entire lifetime of the universe (about 15 billion years). Because the diameter of the observable universe is twice as great as this (about 30 billion light years), there would not have been enough time, in standard Big Bang models, for these widely separated regions to have had any kind of contact with each other (no signal, traveling at the speed of light, could have traveled from one to the other). How, then, could these regions be identical?

By blowing up the universe by such a huge factor, inflation ensures that the curvature of space becomes indistinguishably close to zero (the 'flat' case). If the inflationary model is correct, the observable universe is a tiny portion of the whole, and space appears flat in much the same way as the surface of the planet Earth appears flat if we examine only a tiny portion of it. The huge inflationary factor also offers a solution to the horizon problem. Prior to the epoch of inflation, there would have been time for a sufficiently small volume of space (smaller, say, than 10^{-34} light-seconds across) to iron out any internal differences and become uniform throughout. By blowing up this microscopic volume to become larger than the observable universe, inflation would ensure that the entire observable universe, on the large scale, looks exactly the same.

Inflation also resolves a number of problems relating to particle physics and, by inflating tiny quantum fluctuations to enormous scales, provides a possible mechanism for generating the 'seeds' from which galaxies and larger-scale structures subsequently developed.

Information Handling in Astronomy

In a science such as astronomy, information handling encompasses data collection, analysis and dissemination, as well as the way astronomers publish, interact and communicate, including with other communities, with amateur astronomers and with the public at large.

The main aim of astronomers is to contribute to a better understanding of the universe (as well as of its past and future) and consequently to a better comprehension of the place and role of humans in it.

To this end, together with theoretical investigations, they carry out observations to obtain data that subsequently undergo treatment and studies leading to the publication of results. The whole procedure can include several iterations between the various steps as well as with external fields, non-scientific disciplines, instrumental technologies and information handling methodologies.

In the following, the concept of information will cover the observational material, the more or less reduced data extracted from it, the scientific results and the accessory material used by scientists in their work (bibliographical resources, yellow-page services, and so on), as well as the communications and publications of all kinds.

It should also be noted that, contrary to other scientific disciplines, astronomy has the peculiarity of not being able to interact with the objects it investigates (except for very few bodies of the solar system where *in situ* studies can be carried out by spacecraft). Consequently all our knowledge of the universe has so far depended almost exclusively on the photons reaching us from outer space.

Astronomy has thus to rely on the ingenuity of instrumentalists to conceive and design a whole range of observing tools exploiting at best the latest technologies and the most sensitive detectors to obtain the most relevant and most varied information allowing progress of astronomical knowledge. The current trend is also towards panchromatic astronomy, i.e. combining information from the various wavelength ranges of the ELECTROMAGNETIC SPECTRUM (radio, infrared, visible, ultraviolet, x, γ, …), instead of restricting oneself to specific ranges as used to be the case in the past.

Compared with the past too, ever larger amounts of data are being collected, and the rate will probably continue to accelerate. Instruments such as NASA/ESA's Hubble Space Telescope (HST) or ESO's Very Large Telescope (VLT) are generating or will generate annually a volume of information of the order of terabytes of data. The rate of increase of observations is also matched by the diversification.

Until not so long ago, an astronomer could also work individually from the conception of a project through to the collection and analysis of data. Nowadays, as instrumentation has become more complex, teams of researchers, most often international ones, have become necessary and they quite naturally include technologists or instrumentalists.

At the other end of the chain, the teams are more and more including methodologists, i.e. specialists of information handling. If image processing is a natural consequence of a sophisticated technology, information handling rather qualifies whatever happens to already well-reduced data.

Astronomy and related space sciences have always been at the leading edge of new information technologies, often testing, contributing to and pushing for new developments, be it for the access to databases, the usage of networks or the initial explosion of world-wide web (WWW) sites, as well as for remote observing (spacecraft and ground-based telescopes remotely operated).

The recent dramatic evolution of communication and information technologies had a deep impact on the way the astronomy community interacts and works, in other words on its dynamics, and one can certainly expect more evolution in the future as the corresponding technologies will bring in new potentialities.

Information handling in astronomy thus reflects the way astronomers work and ensures progress of the astronomical knowledge which is then shared with colleague scientists as well as, on a less specialized level, with the significant community of amateur astronomers round the world (also a phenomenon proper to astronomy; see AMATEUR–PROFESSIONAL COLLABORATION IN ASTRONOMY) and with the public at large since cosmic perceptions have always been a fundamental component of human culture and philosophy. Astronomers are of course also deeply involved in EDUCATION at all levels.

As described in the following and as illustrated by figure 1, the information flow in astronomy is far from being a simple linear one. More and more of the processes and corresponding exchanges are performed electronically.

Observing and collecting data

Carrying out professional astronomical observations implies having access to ground-based and space-borne instruments which is a highly, sometimes fiercely, competitive process. Candidates have to submit proposals requesting instrument or spacecraft time with specifications for secondary instrumentation, observing modes and configurations.

The cases must be made not only on the basis of the technical capabilities requested but also with strong

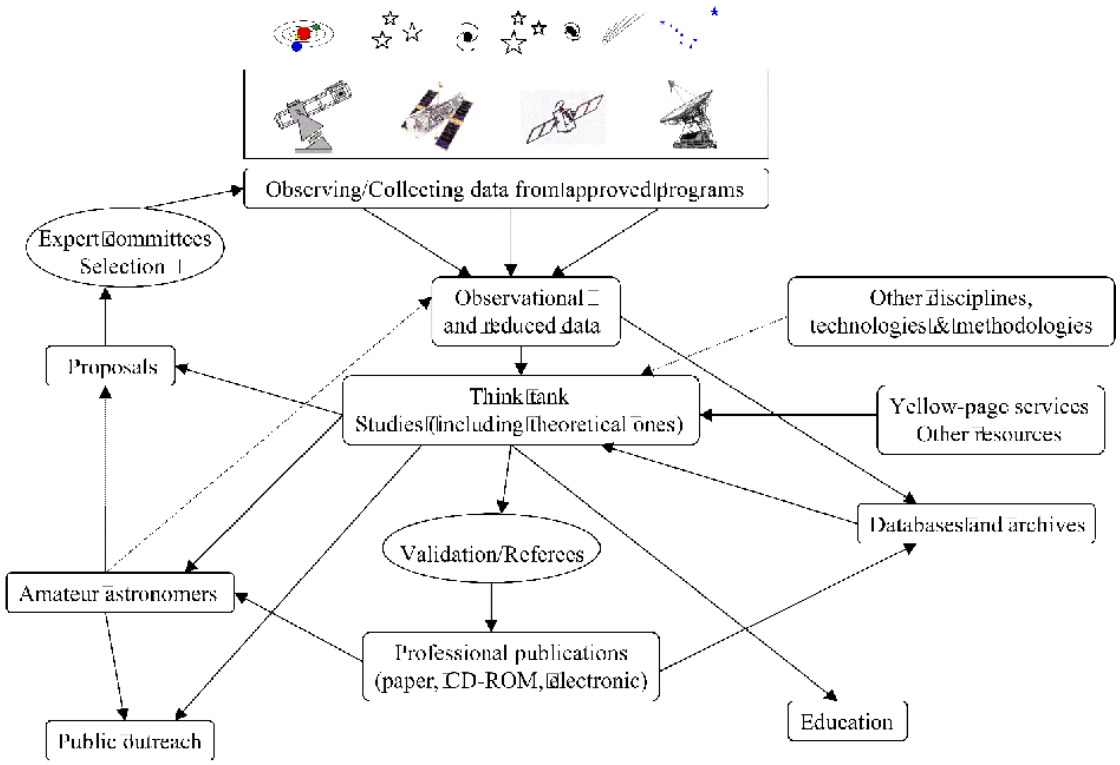

Figure 1. A schematic view of the information flow in astronomy.

references to the scientific achievements aimed at in the light, not only of what has already been achieved, but also of the expertise of the proposers themselves.

Expert committees review the technical feasibility of the proposals and the relevance of the scientific cases. They refer to the available literature (a reason for publishing, see below) and to the past observations carried out with the instrument requested in order to avoid duplication of activities of sometimes highly oversubscribed equipment (hence the need for observing logs, see below).

Oversubscribing factors vary with specific instruments or spacecraft (the new ones and the most efficient ones being generally more sought for), but it is not rare that between five and ten times more observing time is requested than is available. The task of the time allocating committees is therefore not an easy one.

Often astronomers, or even entire teams of astronomers, are encouraged to collaborate with each other, thus to share observing time and the resulting data. Astronomy is by essence an international science and it is quite common to find scientists from all over the world joining efforts in the same team (hence a need for yellow-page services, see below).

Incidentally, service observing (i.e. observations carried out, not by the proposers themselves, but by a team of trained resident astronomers and technicians) is becoming increasingly common in order to maximize return of heavy investments, to optimize instrumental pointing by combining lists of objects ('targets') of several programs and to minimize effects of some adverse factors such as seeing, weather, avoidance zones, solar activity, eclipses, radiation belts and so on.

Service observing also makes it easier to deal with contingency time and with targets of opportunity (i.e. unscheduled events such as discoveries of novae, supernovae, comets and so on). In such cases, quick and efficient interactions with teams of specialists are critical for making the best of such opportunities.

Nomenclature of celestial objects

Cataloging objects properly is a fundamental issue of all astronomical observations and studies. However, when dealing with a study field as populated as the universe, to unequivocally identify the objects at hand is something that is made complicated by several factors.

First of all, the relative positions of objects in the universe—thus in the sky—are not fixed, even if those relative movements are imperceptible to the unassisted eye and often on a human time scale (except again for the solar-system objects).

Second, and all amateur photographers know that effect, the sky looks differently if observed in different wavelength ranges: the infrared sky is not quite the same as the visible one which in turn differs from the radio one, and so on. This results from the fact that celestial bodies radiate the peak of their energy in different

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

wavelength ranges (some stars are red, others are blue; some bodies are strong emitters in the infrared, others in the x range; and so on).

Finally, and maybe most importantly, it all depends at which sensitivity and resolution the sky is observed in a specific wavelength range. The more sensitive is the tool, the more crowded is the sky 'seen' in that range, and the more precise must be the corresponding identification of a given object.

It is not rare either that an object (star, nebula, galaxy,…) become resolved in several, sometimes many, components or elements when observed at a higher resolution. Hence the need for establishing some hierarchical relationships between the designations of those objects as seen in different conditions.

In an excellent environment (i.e. away from the light pollution of densely populated areas), the unassisted human eye can see about 9000 stars brighter than magnitude 6.5 for the whole sky. This corresponds roughly to the Bright Star Catalog (BSC) that provides basic astronomical information. The Henry Draper (HD) Catalog, that goes down to about magnitude 9 (remember that the larger the magnitude, the fainter the object), lists already more than 272 000 stars.

One of the first astronomical space experiments, the Belgian–UK Ultraviolet Sky Survey Telescope (S2/68) on board the TD1 satellite, led to a catalog of ultraviolet fluxes for 31 215 stars collected at the beginning of the 1970s. A decade later, the IRAS Catalog of Point Sources (alone) gathered together some 250 000 well-confirmed infrared point sources observed by the INFRARED ASTRONOMY SATELLITE.

As to the Guide Star Catalog (GSC) for the HUBBLE SPACE TELESCOPE (HST), it contains nearly 19 million objects brighter than magnitude 16, of which more than 15 million are classified as stars. A HUBBLE DEEP FIELD (HDF) typically reveals about 1500 galaxies down to nearly magnitude 30 (i.e. nearly four billion times fainter than the human eye can see) in an area of a few arcminutes (equivalent to a dime seen at a distance of 75 feet). One thus realizes the challenge of unequivocally identifying objects in the sky as the instrumental sensitivity and resolution increase so dramatically.

The nomenclature of astronomical objects follows a number of rules that differ with the objects at hand (see CONSTELLATIONS, STARS, AND DEEP-SKY OBJECTS: NOMENCLATURE).

Solar-system objects, including natural satellites, minor planets and comets, as well as planetary features, are named following recommendations of *ad hoc* professional committees confirmed by the INTERNATIONAL ASTRONOMICAL UNION (IAU).

Discoveries of new bodies are handled by the Central Bureau of Astronomical Telegrams (CBAT) and the Minor Planet Center (MPC) that assign provisional designations until ratification by the IAU (for example, lunar craters named after outstanding scientists, asteroids bearing names selected by their discoverers, and so on). Comets are nowadays the only bodies still receiving the names (up to three) of their discoverers, together with an alphanumerical identification. The CBAT also informs on discoveries of supernovae as well as other remarkable discoveries, events and celestial objects.

A whole book would be necessary to describe in details all the systems used to designate stars and non-stellar objects. If a few bright ones have ancient historical names (Sirius), other designations include constellation memberships (α CMa), memberships of declination zones (–18°1345), sequential discovery numberings (V341 Sco), references to wavelength ranges (Sco X-1), to object natures (PSR 0031-007), to observatories, instruments or spacecraft (Lick Hα 52), to larger objects (NGC 125-6), to astronomer names (Barnard's star), and so on, not to forget the most common identifications: sequence numberings in hundreds of astronomical catalogs and observing logs available. In other words, most celestial objects have just numbers and positions on the sky.

A few words are in order here on a fashion that has been developed by non-official organizations on naming celestial objects and selling corresponding certificates. The fact is that such names have no formal or official validity whatever. Astronomers and their representative organizations dissociate themselves entirely from such commercial practices of selling fictitious names of surface features, of stars and of celestial bodies.

The IAU is the sole internationally recognized authority for naming them. Those names are not sold, but assigned according to internationally accepted rules, recognized and used by scientists, space agencies and authorities worldwide.

Catalogs, surveys, observing logs and archives

As introduced above, catalogs can be organized according to object types (e.g. planetary nebulae, quasars, pulsars, …), according to the type of data they offer (e.g. proper motions, photometric indices, spectral types, …), or both. So many catalogs are available nowadays that it is out of the scope of this article to detail them. Refer, however, to the services maintained by the data centers (see below and the list of URLs at the end of the article).

Surveys refer more to systematic coverages of the sky with specific instruments, such as the famous Palomar Observatory Sky Survey (POSS), which was in fact a professional photographic atlas of the sky as seen in two colors by the Palomar Schmidt telescope.

Important catalogs nowadays are also what is called the observing logs gathering together the details of the observations carried out with a specific instrument (objects observed; date, time, duration of observations;

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

instrumental specifications and/or configurations; and so on). They are in general linked to instrumental archives.

Archiving is also a critical issue in astronomy, basically because practically all celestial objects are variable with time in a way or another and also, as seen earlier, because we are essentially passive observers of the universe and not experimenters who would be able to recreate at any time situations for further investigations.

The memory of past observations is thus fundamental for future studies since furthermore it is not known for what purposes the next generations of astronomers would use the data. For a couple of decades now, the funding of all big new projects has included provisions for comprehensive image processing, adequate archiving and further exploitation of the archive after the possible termination of the mission. This might sound an obvious policy, but it is in fact a rather recent approach.

The challenge here is of a technical nature as the average lifetime of storage media is about 4 yr and about 3 yr for the user interfaces. Thus any long-term archiving policy has to make provisions for regularly transfering data on new material.

Dababases and information hubs

Beyond catalogs and collections of catalogs, extremely powerful databases are now available. The data centers themselves have become information hubs providing a whole spectrum of world-wide services.

The Strasbourg astronomical Data Center (CDS) (figure 2) has been a long-time pioneer and is nowadays recognized as the world leader in these matters.

In the early 1970s, a number of European institutions decided indeed to collaborate and to create a data center at Strasbourg Observatory with the daunting task of establishing an enormous table of synonyms between all catalog identifications. This was definitely aimed at avoiding the repetition of a couple of situations where two qualified astronomers studied and published papers on the same object, but under different identifications and without realizing it.

However, more interestingly, this was allowing, with a single object name, access to all other identifiers, plus to the data listed in the various catalogs. As CDS also set up a comprehensive and very successful bibliographical object-oriented database, the references of the papers dealing with that object were immediately available by the same token. The popular Simbad database was born.

Simbad holds today more than 2 200 000 objects under about 5 500 000 identifiers, together with more than 105 000 bibliographical references including about 3 000 000 object citations. Anyone starting studying seriously an astronomical object must pay a visit to Simbad first.

Figure 2 shows other components of CDS's information hub. VizieR is a search-and-shop individual-catalog service, with also access to large tables published in professional journals. Aladin is an interactive digitized sky atlas. Besides the references of Simbad, the CDS bibliographical service provides also access to abstracts of several major journals (see also ADS hereafter). The dictionary of nomenclature gives references and details on usage for more than 4000 different catalog acronyms. AstroGlu is a discovery tool helping to locate database servers providing relevant information.

Last, but not least, the StarPages are a set of permanently updated yellow-page resources providing detailed information on astronomy-related organizations (StarWorlds: about 6300 entries, more than 5500 WWW links), as well as on individual astronomers and related scientists (StarHeads: more than 5200 WWW home pages). They offer also access to an enormous dictionary (StarBits: about 140 000 entries) of abbreviations and acronyms related to astronomy and associated space sciences. The master files for StarWorlds have been used to produce figure 4 (see below).

A few other multipurpose resources deserve also a mention in this section.

The NASA/IPAC Extragalactic Database (NED) has been built around a master list of extragalactic objects for which cross-identifications of names have been established, accurate positions and redshifts entered to the extent possible, and some basic data collected. Bibliographic references relevant to individual objects have also been compiled.

The Astrophysics Data System (ADS) is a NASA-funded project whose main resource is an abstract service (about half a million abstracts for astronomy and astrophysics only), together with links to scanned images of over 40 000 journal articles. ADS provides also access to astronomical data catalogs and data archives, thereby making data collected by NASA space missions available to astronomers. It offers also access to the StarPages.

The National Space Science Data Center (NSSDC) provides access to a wide variety of astrophysics, space physics, solar physics, lunar and planetary data from NASA missions, together with some complementary data.

The Canadian Astronomy Data Centre (CADC) and the Astronomical Data Analysis Center (ADAC) at the National Astronomical Observatory of Japan (NAOJ) are national resources offering access to a number of catalogs, databases and archives.

Data processing

Until not so long ago, data processing consisted essentially in photographic-plate scanning and in reduction of raw photometric data from punched papertapes.

Nowadays, with the omnipresent digitization and multidimensionality of collected data, one rather speaks of image processing and a whole treatise could be devoted to it.

Indeed the time seems definitely gone, at least with the big instruments, when astronomers were coming themselves to the telescope (or ground observatory for a spacecraft) and later returning home with unprocessed data. The advanced experiments have developed their own specific image processing which is now part of the projects themselves since the development phase.

Several comprehensive image handling systems have however been developed such as ESO's Munich Image Data Analysis System (MIDAS) and NOAO's Image Reduction and Analysis Facility (IRAF). They can be considered as general-purpose software systems for the reduction and analysis of astronomical data and are regularly upgraded.

Complementary resources would include specific software packages and libraries (such as statistical ones), spectral line compilations, abundance libraries, opacity tables, and so on. A network such as Starlink helps UK-based astronomers to reduce and analyze their observations.

It is certainly worthwhile to mention here that astronomers have introduced the Flexible Image Transport System (FITS) which is a general way to encode both definitions of data and the data themselves and which is machine independent. The FITS format has been quickly recommended for interchange of image data between all observatories—and is now in use even outside astronomy.

Publishing and information sharing

Publishing is not only motivated by the noble aims of educating and information sharing but also strongly conditioned by career constraints involving recognition, a necessity that should not be underestimated. Recognition is sought for getting positions (i.e. grants and salaries), for obtaining acceptance of proposals (e.g. leading to data collection) and for achieving funding of projects (allowing materialization of ideas).

The pressure for recognition has contributed to the strong increase of professional publications (see figure 3), together with other factors such as the expansion of the astronomy community itself (especially after the beginning of the space age), the multiplication of large instruments and spacecraft equipped with always faster, more diversified and more efficient detectors, and so on. Commercial publishers have also put on the market more journals which were as many additional communication outlets.

The major professional journals use the peer-review procedure ('refereeing') for accepting, amending or rejecting submitted contributions. Albeit a matter of regular debates (on the principle itself as well as on the way it is conducted), the refereeing process has been so far the best one (or the less questionable one) to publish contributions with validated content, i.e. an assurance of good-quality, novel results obtained by reproducible experiments, calculations or analyses on which enough details are provided.

The most important general professional journals include the *Astrophysical Journal* and the *Astronomical Journal* published by the *American Astronomical Society*, the *Monthly Notices of the Royal Astronomical Society*,

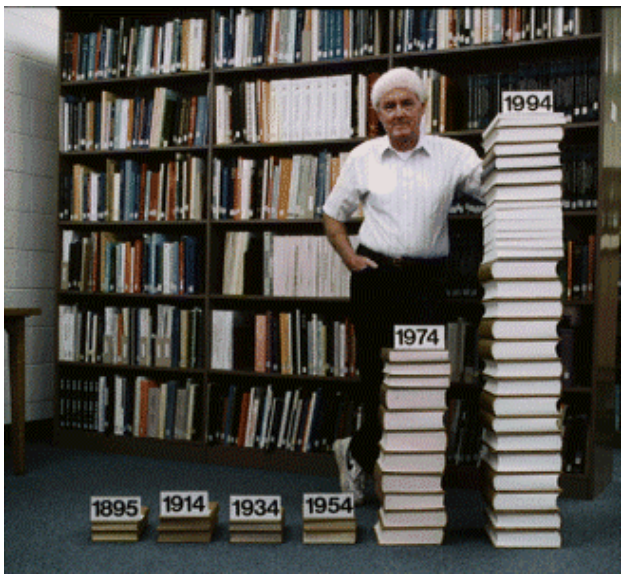

Figure 3. An illustration of the dramatic increase of astronomical literature over the past decades. Helmut A Abt, Editor-in-Chief of the *Astrophysical Journal*, is standing next to stacks of that leading professional publication (courtesy the *National Optical Astronomy Observatories, NOAO*).

and *Astronomy and Astrophysics* resulting from the merging in 1969 of a number of European professional journals (see also ASTRONOMICAL SOCIETIES AND PUBLICATIONS).

Astronomers communicate also via a whole spectrum of publications ranging from informal newsletters to books gathering together review papers by the best specialists on specific topics. Conferences, colloquiums, workshops and meetings of all kinds provide also efficient ways of exposing oneself to both excellent review talks and presentations of works in progress. The corresponding proceedings are published by commercial publishers, by learned societies, by research institutions or even by individuals, reasonably soon after the events.

As described in the following section, publishing is nowadays increasingly done electronically, or, better said, there is more and more of diversified publishing, i.e. of information available on different media (paper, CD-ROM, web sites, and so on). These media are not excluding, but complementing, each other. Several journals have an electronic counterpart.

As mentioned earlier, professional astronomers are also contributing substantially to less specialized publications, mainly directed towards amateur astronomers and the public at large. Many countries have their own such national journal, but *Sky & Telescope* is probably the magazine with the largest audience world-wide (see also MEDIA).

Electronic astronomy

As mentioned already, more and more of the information exchanges in astronomy are done electronically, both dynamically (e-mail) and passively (web sites). Electronic handling is particularly well adapted to the fluid and living nature of today's information material, to the digitized nature of most data and to the efficiency of contacts between collaborators spread over the world, as well as to the retrieval of information from the information hubs. It also makes easy the various interactions upstream and downstream, and allows diversified publishing.

Figure 4 gives an idea of the distribution, at the time of writing this article, of the astronomy-related organizations using e-mail and/or having a web site. Together with the general world distribution, more detailed views are displayed for North America and Western Europe.

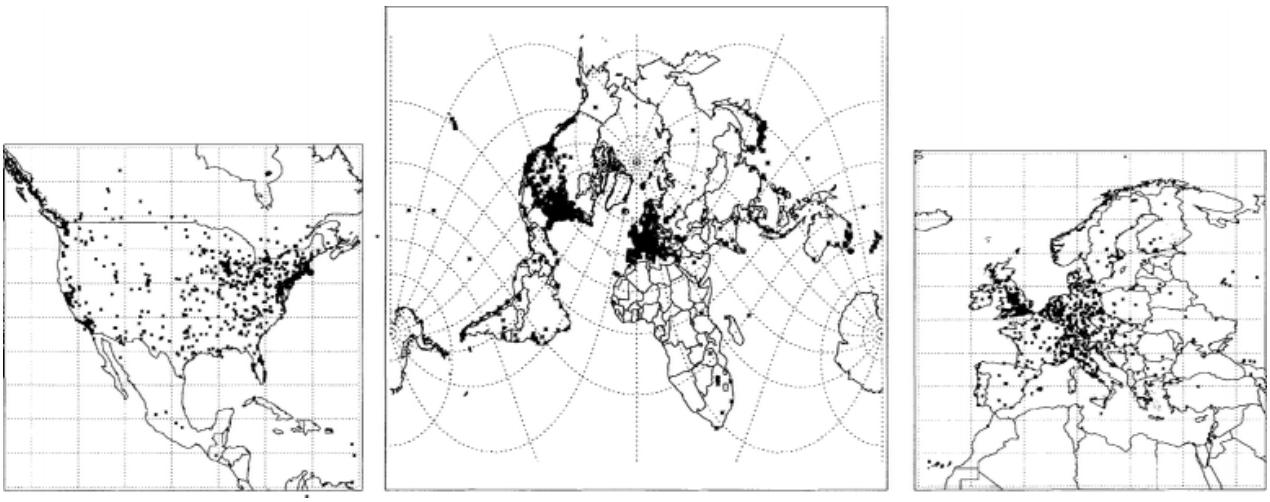

Figure 4. Geographical distributions (North America, World, Western Europe) of astronomy-related organizations (all categories) with electronic facilities (e-mail and/or web pages) in April 1999.

The largest concentrations are located in Europe and in the USA (Northeast and California), with a few nuclei in Australia, India, Japan, New Zealand, as well as a few spots in South America. A striking feature of the central map is the desperate emptiness of the African continent. A similar comment is also applicable to quite a number of the so-called third-world countries.

In Western Europe, it is striking how France, Portugal and Spain have significantly much lower densities than their European neighbors, obviously lagging behind as to the penetration of the internet and the WWW, a few years after the electronic medium started spreading quickly over the world.

The 'electronization' of astronomical information handling is, however, not a bed of roses. New facilities and new possibilities bring in naturally new questions, new challenges and new problems that have to be faced, especially at the ethical level (proper credits of downloaded material, for instance), as well as at the legal (financial and copyright policies, electronic signatures, for instance) and educational (training of young and not-so-young people) ones, without forgetting the security and the fragility of the material delivered via the electronic medium—a very worrying factor for many people.

The most demanding challenge, however, arises probably from the enormous quantity of information easily reachable (and providable) by everybody nowadays, as discussed in the following section.

The information retrieval challenge

At ACM97, the conference celebrating the 50th anniversary of the Association for Computing Machinery, the Nobel Prize laureate Murray Gell-Mann called attention to the fact that, with the digital age producing an 'immense sea of data that threatens to drown humanity', people needed to adapt how they think so that true knowledge can be distilled from the deluge.

> 'We hear, in this dawn of the so-called information age, a great deal of talk about the explosion of information and new methods for its dissemination. It is important to realize, however, that most of what is disseminated is misinformation, badly organized information or irrelevant information. How can we establish a reward system such that many competing but skillful processors of information, acting as intermediaries, will arise to interpret for us this mass of unorganized, partially false material?'

That challenge is probably the most critical one currently in the field of information handling—and astronomy is facing it too.

We shall have to rely, indeed, on the wisdom of providers and users of electronic information, as well as on the various intermediaries (compilers, information hubs,…) and on the learned societies, committee experts and so on to take this into account, to put, more than ever, the emphasis on validated and authenticated electronic information, and to reward appropriately the scientists who are or will dedicate a full-time job to such activities.

The quality of resources as well as their maintenance must be continuously improved from lessons learned with time and using the most adequate tools. Generally speaking, information has to be collected, verified, de-biased, homogenized and made available not only in an efficient way but also through reliable channels. Sophisticated techniques cannot save the extensive background, unrewarding and very careful work which is indispensable for the compilation of a valuable resource. One could never stress enough the importance of this obscure daily work consisting of patiently collecting data, checking information and updating it. This has also to be carried out by knowledgable scientists or documentalists and cannot be delegated to inexperienced clerks.

Efficient search engines working on validated and authenticated material must enable finding information looked for, if available at all, and whether it relates to celestial objects, to data, to bibliography or to the vast coverage by yellow-page services. That information must be of good quality, relevant and on target. The best search engines available today and the corresponding organizations have been mentioned in this article.

As technology leaders agree that changes are the only sure thing about computing and communications in the next decades, we can certainly expect further modifications on the information handling in astronomy and consequently on the sociodynamics of the astronomy community itself.

Useful URLs

For WWW access, here are—in alphabetical order—the URLs of the most relevant organizations and resources mentioned in the article. Most of them are collaborating with each other and are hosting mirror pages of their partners. Complementary resources are also generally available from the sites.

Bibliography

Because of the quick evolution of information technologies nowadays, and because of the impact they have on the dynamics of the astronomy community, some aspects of the most recent compilations and reviews could become rather quickly outdated. The basic principles will largerly remain unchanged, however, and the following books could be recommended as possible further, more technical, reading.

Boroson T, Davies J and Robson I (ed) 1996 *New Observing Modes for the Next Century* (San Francisco, CA: Astronomical Society of the Pacific)

Egret D and Albrecht M A (eds) 1995 *Information & On-Line Data in Astronomy* (Dordrecht: Kluwer)

Heck A (ed) 1997 *Electronic Publishing for Physics and Astronomy* (Dordrecht: Kluwer)

Heck A and Murtagh F (ed) 1993 *Intelligent Information Retrieval: The Case of Astronomy and Related Space Sciences* (Dordrecht: Kluwer)

Jaschek C 1989 *Data in Astronomy* (Cambridge: Cambridge University Press)

Series of specialized conferences provide also sources for advanced material. See for instance the following as well as the numerous references quoted therein:

- the Astronomical Data Analysis Software and Systems conferences (proceedings published by the Astronomical Society of the Pacific, San Francisco),
- the Astronomy from Large Databases conferences (proceedings published by the European Southern Observatory, Garching),
- the Data Analysis in Astronomy ('Erice') workshhops (proceedings published by Plenum Press, New York, and World Scientific, Singapore),
- the Converging Computing Methodologies in Astronomy workshops of the European Science Foundation (proceedings published in Vistas in Astronomy).

Infrared Arrays

Infrared arrays are small electronic imaging devices subdivided into a grid or 'array' of picture elements, or pixels, each of which is made of a material sensitive to photons (ELECTROMAGNETIC RADIATION) with wavelengths much longer than normal visible light. Typical dimensions of currently available devices are about 27–36 mm square, and formats now range from 2048×2048 pixels for the near-infrared detectors down to about 128 × 128 pixels for the mid- and far-infrared regions. These imaging devices have completely revolutionized INFRARED ASTRONOMY since their introduction in the late 1980s because they provide images and spectroscopic information about regions of space that are not accessible to visible light detectors (see also INFRARED IMAGERS). Such regions include the dusty, gaseous clouds where star formation occurs, the obscured center of the Milky Way some 28 000 light-years from the solar system, as well as the most distant galaxies in the universe. Distant objects must be studied at infrared wavelengths because the Hubble expansion of the universe has shifted their spectra far into the red.

While there is some similarity between infrared arrays and silicon CHARGE-COUPLED DEVICES (CCDs), there are also fundamental differences. Infrared arrays cannot use pure silicon as the detector material because it is not sensitive to light of wavelengths longer than 1.1 μm, no charge-coupling is used to extract the signals, and much lower cryogenic temperatures are needed to operate these devices. Infrared arrays require cooling to temperatures between liquid nitrogen (77 K) and liquid helium (4 K), depending on their wavelength range of operation.

To generate an image, all infrared array detectors must convert radiation into electrical charge by absorbing a photon. The material used to detect the photon is a semiconductor, that is, a crystalline material with electrical conductivity properties intermediate between that of a good conductor like copper and an insulator like glass. Silicon is the best known semiconductor. Other examples include germanium (Ge), gallium arsenide (GaAs) and indium antimonide (InSb). Each is characterized by a crystal structure with an energy bandgap which separates a conduction band from the normal valence band of the atoms. The absorption of a photon of sufficient energy excites an electron from the valence band into the conduction band. The smaller the bandgap, the lower the photon energy needed and the longer the wavelength of radiation that can be detected by the material. If the bandgap energy (EG) is expressed in electron-volts, then the longest wavelength that can be detected is given by 1.24 μm/EG. The bandgap varies slightly with temperature, but typical values are 1.1 eV for Si, 0.67 eV for Ge, 0.18 eV for InSb

There are two classes of semiconductors used in infrared photon detection; intrinsic and extrinsic. In an intrinsic semiconductor crystal, a photon with sufficient energy creates an electron–hole pair when the electron is excited to the conduction band, leaving a positively charged site or 'hole' in the valence band; this is the same physical process that operates in a silicon CCD to detect photons. Common infrared intrinsic materials are germanium (Ge), lead sulfide (PbS), indium antimonide (InSb) and mercury cadmium telluride (HgCdTe). As already shown above, these have bandgap energies less than silicon and therefore have a longer cut-off wavelength. Extrinsic semiconductors are intrinsic materials, typically silicon and germanium, which have been 'doped' with impurity atoms so that a very low energy photon, with insufficient energy to excite an electron–hole pair directly, can still cause an excitation from an energy level associated with the impurity atom. In effect, a stepping stone is placed in the energy bandgap of the intrinsic material. Examples of extrinsic semiconductors used in astronomy applications are arsenic-doped silicon (Si:As) which can detect photon wavelengths as long as 23 μm, and gallium-doped germanium (Ge:Ga) which goes all the way to 115 μm.

Another kind of infrared array device is found frequently in industrial surveillance applications, this is the platinum silicide (PtSi) array. A PtSi array is based on the Schottky barrier principle. When a metal such as platinum silicide is brought into contact with p-type silicon, the result is an asymmetric potential barrier. Conduction holes in the metal must now overcome a slightly higher barrier to enter the valence band of the semiconductor. The barrier height is determined by the contact potential and can be less than the semiconductor bandgap; for PtSi the cut-off wavelength is 5.6 μm. Although more easily manufactured into large-format arrays, because it is an all-silicon process, the photon detection efficiency of these detectors is rather low and their use in astronomy has been quite limited so far.

All of the detectors mentioned so far are photon detectors. For completeness, a fundamentally different kind of detector should be mentioned. It is the bolometer, which belongs to a class called thermal detectors. These devices absorb photons and convert their energy to heat and the heat energy is detected through some change in physical properties such as conduction of the material. Only the energy deposited by the photons is important, not their wavelength. Semiconductor bolometers are the most highly developed, but bolometer arrays have tended to be very small (30 × 30 pixels) so far, compared with near-infrared arrays.

Any infrared array detector must perform three functions:

- store the accumulated electrical charge at the site of generation, i.e. in a pixel;
- transfer the charge on each pixel to an outlet; this task is called multiplexing;
- convert charge to a voltage which can then be readily digitized into a number for storage in a computer.

All infrared arrays separate the functions of detecting infrared radiation from that of multiplexing the resulting

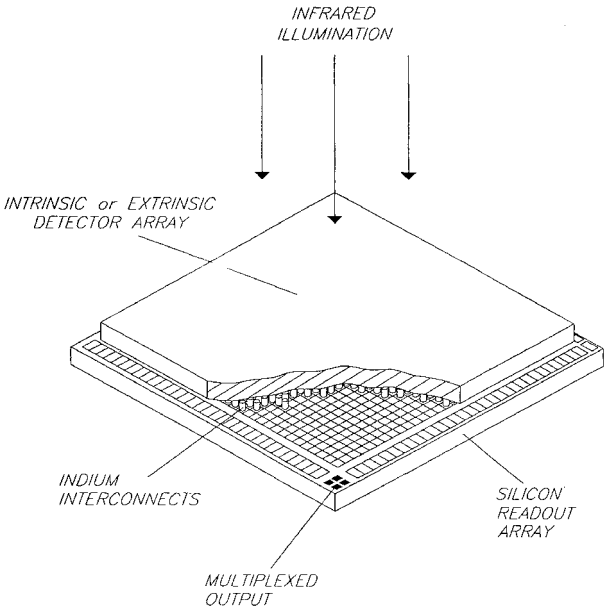

Figure 1. A schematic diagram illustrating the hybrid nature of infrared arrays. The upper slab is the infrared detector and the lower slab is the silicon-based readout device. Interconnections are made with 'bump' bonds of indium.

electrical signal, with the latter task going to silicon. Infrared arrays are like 'sandwiches' in which the upper slab is the infrared sensor (e.g. InSb, HgCdTe; Si:XX, Ge:XX, where XX represents the element used for doping, or PtSi), and the lower slab is a silicon multiplexer of some sort. A special array of 'switches' made from silicon field effect transistors (FETs) in microscopic form is typically used in the lower slab to access the signal from each IR pixel above.

The infrared-sensitive part of an infrared array is a tightly packed grid of individual pixels with minimum dead space between them (figure 1). Both slabs are provided with a grid of electrical connections in the form of tiny raised sections, referred to as 'bumps', of a soft electrical conductor called indium; indium remains soft at low temperatures. The slabs are literally pressed together to enable the indium bumps to mate. Gaps between the bumps are usually back-filled with an epoxy to help maintain the integrity of the sandwich, especially through thermal cycles to low temperatures. Charge storage may occur on the junction capacitance of the IR sensor itself or on a separate storage capacitor associated with the silicon circuitry. Infrared arrays are harder to manufacture than silicon CCDs and consequently more expensive. The leading suppliers of astronomical devices are Rockwell International, Boeing and Raytheon/SBRC in the United States. Several other companies provide infrared arrays suitable for surveillance applications.

Either the upper slab is constructed on an IR-transparent substrate, such as the sapphire substrate used for the HgCdTe arrays, or the bulk semiconductor is physically thinned to enable photons to penetrate the backside to the pixel locations on the inner face, as in the case of the InSb arrays. When the absorption of a photon with a wavelength shorter than the cut-off wavelength generates an electron–hole pair in the semiconductor, at the location of the pixel, the pair is immediately separated by an electric field which can be applied externally or internally or both. For example, in near-infrared arrays of InSb and HgCdTe, the electric field results from a reverse-biased pn junction or photodiode. The depletion region produced by the reversed-bias junction acts like a capacitor (C) which is discharged from its initial state (the full reverse-bias voltage V) by the migration of the electrons and holes; in effect, photo-generated charges are being 'stored' locally at each pixel. The maximum amount of charge (expressed as a number of electrons) which can be stored is given by $Q = CV/e$, where e is the charge on the electron (1.6×10^{-19} C). Of course, there must be a small perimeter or boundary around a pixel to define each individual photodiode, and this region cannot be too large otherwise there is a serious light loss, nor can it be too small because then there will be cross-talk between pixels, i.e. the charge from one pixel can be collected by an adjacent pixel. When the capacitor is completely discharged, the storage well is full and the pixel is said to be 'saturated'. No damage occurs, but charge accumulation ceases and the signal is no longer proportional to the number of photons detected.

Charge on each pixel is said to be 'read out' by sequentially connecting its signal to a common output line, or bus, leading to one or more output amplifiers. Multiple readout amplifiers are common in infrared arrays because thermal emission of radiation by the telescope optics and the sky itself introduces a significant 'background' light at wavelengths longer than about 2.5 μm. This background photon emission fills up the storage wells sufficiently rapidly that it helps to expedite the readout process by having more than one amplifier. On-chip circuits called 'shift registers' perform the readout and multiplex sequencing. In the most common and successful multiplexer designs, the 'unit cell' of an infrared array contains a silicon field-effect transistor (FET) used as a source-follower amplifier, essentially providing a buffer for the accumulated charge in the infrared pixel. The term used to describe this structure is SFD (source follower per detector). There is also an electrical noise associated with this circuitry which results in an unwanted 'readout' noise.

The voltage change across the detector capacitance is applied directly to the input gate of the silicon FET (across the indium bump interconnect), which in turns relays the voltage change to one or more output lines when it is switched on or 'addressed' to do so. The output voltage is amplified and digitized by external circuits and a number for the signal in that pixel is stored in the corresponding location in a computer file.

Infrared array detectors are not based on the charge-coupling principle of the silicon CCD. This is an important distinction which has some practical

implications. For example, IR arrays do not 'bleed' along columns when a pixel saturates, and 'bad' pixels do not block off others in the same column. Also, since the pixel charge does not move, 'non-destructive' readout schemes are possible and are very effective in reducing unwanted electrical noise. Some near-infrared arrays manufactured by Rockwell International using HgCdTe detectors have achieved readout noise levels as low as two to three electrons (equivalent) using multiple non-destructive measurements to average down the noise, but noise of 15–30 electrons is more common. On the other hand, CCD features such as on-chip charge binning, charge-shifting and drift-scanning are not possible with infrared arrays.

Most long-wavelength (i.e. wavelengths >8 μm) arrays use extrinsic silicon detectors employing a technology called impurity band conduction (IBC). In an IBC device, a heavily doped infrared-active layer is placed in contact with a pure (undoped) epitaxial (thin) layer, the blocking layer, which is isolated by an oxide (insulating) layer from metal contact pads and the device is usually back-illuminated. These arrays are also called blocked impurity band (BIB) devices. Because of the high donor density, the applied (bias) electric field causes a migration of holes toward the (negative) metal contact forming a depletion region similar to that in the photodiode (pn junction) devices used at shorter wavelengths.

For wavelengths longer than 40 μm there are no appropriate shallow dopants for silicon and therefore extrinsic germanium must be used. There are a number of problems with the use of germanium. For example, to control dark current the material must be relatively lightly doped and therefore absorption lengths become long (3–5 mm). Since the diffusion lengths are also large (250–300 μm), then pixel dimensions of 500–700 μm are required to minimize 'cross-talk' of the signals between pixels. Large pixels imply higher hit rates for cosmic rays, especially for space applications, which in turn means that the readout device must be very low noise so that the background limit is reached in the shortest possible exposure time. But a large detector pixel means a large capacitance and more noise. Also, the photoconductive gain is inversely proportional to the interelectrode spacing, resulting in poor quantum efficiency unless side-illuminated detectors with transverse contacts are used. Finally, because of the very small energy bandgaps, these detectors must operate at liquid helium temperatures well below the silicon 'freeze-out' range. Despite these challenges, small format arrays with response out to beyond 200 μm have been constructed for infrared space missions such as SIRTF.

Since very narrow bandgap semiconductor crystals are harder to grow, it is tempting to seek a method of 'engineering' small bandgaps in wide-bandgap material such as gallium arsenide (GaAs). Using GaAs and AlGaAs junctions it is possible to create a 'quantum well' or potential associated with either the conduction or the valence band. The quantum well is equivalent to the particle-in-a-box problem in quantum mechanics and so the well will contain energy levels or sub-bands. The energy difference between these levels is very small compared with the normal bandgap. Transitions between the sub-bands provide the infrared detection process. Such detectors are currently under development.

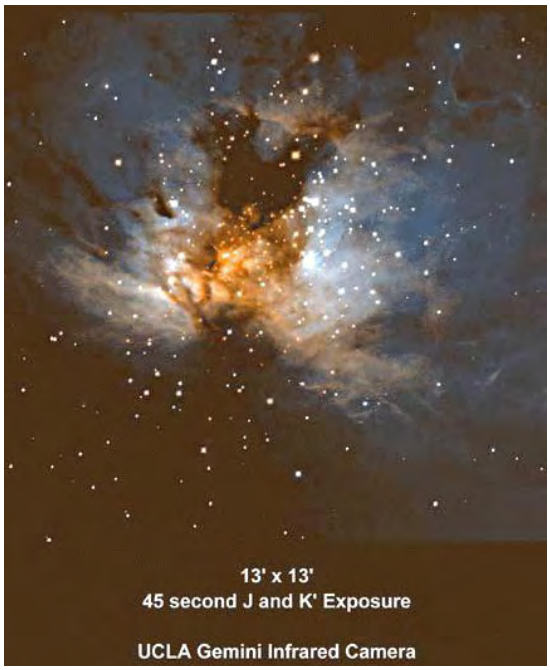

Figure 2. The star-forming region NGC2024 near Zeta Orionis in Orion. The image is a three-color composite of near-infrared bands at 1.2, 1.65 and 2.2 μm represented as blue, green and red respectively. The central region of this nebula appears black in optical photographs due to absorption by dust grains. Infrared images reveal a dense cluster of very young stars.

As an illustration of their use, figure 2 shows an image obtained with an infrared array camera.

Infrared Astronomy

The infrared part of the electromagnetic spectrum covers the wavelength range from about 1 mm (300 GHz) to 1 μm (300 THz). The infrared (IR) band is usually subdivided into the sub-millimeter (1 mm to 0.3 mm), the far- (0.3 mm to 50 μm, FIR), mid- (50 μm to 10 μm, MIR) and near-infrared (10 μm to 1 μm, NIR). At the long-wavelength end it connects to the radio domain and at the short end to the optical. In the FIR and most of the MIR domain astronomical sources cannot be observed from the ground. The other domains exhibit atmospheric windows of varying depth. Astronomical sources observed in the IR exhibit radiation temperatures of a few thousand to a few degrees kelvin. The most prominent sources are PLANETS, late-type stars, interstellar dust and gas clouds (see INTERSTELLAR MATTER), infrared luminous galaxies, the 3 K COSMIC MICROWAVE BACKGROUND and non-thermal extragalactic radio sources (QUASARS). Important reasons to carry out observations in the infrared are that the effect of dust extinction is minimized in this wavelength domain, the determination of the total luminosity of dust-enshrouded objects, and the fact that the visible to ultraviolet spectra of highly redshifted galaxies and quasars are shifted into the infrared while these objects become unaccessible in the optical due to extinction by hydrogen below a rest wavelength of 91 nm.

History

In 1800 Sir John HERSCHEL dispersed solar light through a glass prism onto several thermometers. Thomas Edison observed a total solar eclipse in 1878 in the infrared. In the early 1900s the Moon, planets and bright stars were observed in the infrared by S Pettit and E Nicholson. This work was continued by the systematic and extensive infrared studies of planets and stars by G KUIPER and H L JOHNSON in the 1950s (see Low and Rieke 1974). Frank J Low fully opened the field to astronomy in the early 1960s by inventing a low-noise gallium-doped germanium bolometer. In the following years the development of array detectors based on InSb and HgCdTe (up to 1024 $\times$ 1024 pixels) as radiation-sensitive substances determined the progress in the near-infrared. Balloon, airborne and satellite based observatories allowed measurements even at far-infrared wavelengths. Dedicated telescopes and sensitive bolometers and heterodyne receivers based on Schottky and SIS diodes opened the submillimeter domain.

Telescopes and observational techniques

The short NIR domain is contaminated by variable non-thermal atmospheric line emissions and with the exception of the NIR shortward of 2 μm the infrared is dominated by the thermal emission of the local background that includes the partially transparent atmosphere and all optical elements at the ambient temperature. Sensitive measurements are only possible from high mountains, balloons, airplanes or satellites using cooled instruments, detectors or (in space) even cooled telescopes. To further suppress the thermal background, secondary telescope mirror sizes are kept as small as possible and in the MIR the solid angle on the sky that is encompassed by individual detector elements is minimized in order to suppress the atmospheric thermal radiation. A novel technique in the short NIR is 'OH background suppression' which involves instrumental blanking of the OH line emission at a high spectral resolution. Stable background suppressed observations include observational techniques such as 'nodding' (measurements at alternating positions by moving the telescope back and forth) and 'chopping' (measurements at alternating positions by moving, for example, the secondary mirror at a frequency $\geq$1 Hz). The flux calibration is usually performed via a comparison with local radiation sources (black-bodies) at ambient ($\sim$300 K) or liquid nitrogen ($\sim$77 K) temperature or astronomical standards like planets, quasars or reference stars.

Usually the angular resolution of an optical/infrared telescope is limited to about one arcsecond due to the turbulent atmosphere. In order to obtain diffraction-limited images from the ground at several telescopes 'adaptive optics' has been employed (Alloin and Mariotti 1994, Tyson 1991). Traveling through the Earth's atmosphere the initially plane wave front from the object is distorted and measured at the telescope in the optical with a Shack–Hartmann or curvature wavefront sensor (see Tyson 1991). This signal is then used to control a deformable mirror that can correct the wavefront distortions in the NIR. The resulting images have a diffraction-limited part that contains typically up to 60% of the light. The angular resolution A in arcseconds that can be achieved depends on the observing wavelength λ in micrometers and the diameter D of the telescope in meters and can be calculated via $A(\text{arcsec}) \sim 0.206 \times \lambda/D$. For an 8 m class telescope it is of the order of 0.06 arcseconds at a wavelength of 2.2 μm. Combining different telescopes interferometrically subarcsecond angular resolutions can be obtained in the submillimeter domain (Downes 1989, Watt and Webster 1990). Interferometric measurements can also be applied in the MIR and NIR domain. They provide high-accuracy astrometry and information on stellar diameters and orbital elements of multiple stars.

Telescopes

A large amount of information has been gained with INFRARED TELESCOPES in the 2 to 4 m class (e.g. the Infrared Telescope Facility, IRTF, of NASA or the New Technology Telescope, NTT, of the EUROPEAN SOUTHERN OBSERVATORY, ESO). Large-aperture telescopes with dedicated NIR and MIR facilities are the Keck Telescope in Hawaii (10 m diameter) the ESO Very Large Telescope (VLT) on Paranal in Chile (four 8 m telescopes). Others like the LARGE BINOCULAR TELESCOPE (LBT; two mechanically coupled 8.4 m telescopes) at the MT GRAHAM INTERNATIONAL OBSERVATORY in Arizona, the multinational GEMINI OBSERVATORY twin 8.1 m telescopes in Chile and Hawaii, or the 8.3 m diameter

SUBARU TELESCOPE of Japan in Hawaii will soon come into operation. In addition to space missions that are summarized below, MIR and FIR observations have been carried out using the Kuiper Airborne Observatory (KAO) with a 36 in telescope on board a C-141 airplane at a height of up to about 14 km. This observatory will be followed by SOFIA (the USA/German Stratospheric Observatory for Infrared Astronomy), a 2.5 m mirror on board a Boeing 747. In the submillimeter domain large single-dish antennas like the NOBEYAMA RADIO OBSERVATORY 40 m dish in Japan and the 30 m telescope of IRAM (INSTITUT DE RADIO ASTRONOMIE MILLIMÉTRIQUE) in Europe and the JAMES CLERK MAXWELL TELESCOPE (JCMT) in Hawaii (15 m), as well as several millimeter wavelength interferometry arrays in the USA, Europe and Japan have contributed to the investigation of line and continuum emission of gas and dust in our own and external galaxies in the local universe and at cosmological redshifts. Further progress will be achieved in the near future via the infrared optimized NGST (Next Generation Space Telescope), interferometric arrays with a very large collecting area like the ALMA (the ATACAMA LARGE MILLIMETER ARRAY in northern Chile), as well as large bolometer and spectrometer focal plane array receivers for single dish telescopes.

Detectors

A broad variety of detector techniques is required in the infrared (e.g. Rieke 1994). In the NIR and MIR range large-format focal plane detector arrays are used. Arrays that use HgCdTe as IR sensitive material are hybrid structures. They have been built using molecular beam epitaxy and liquid phase epitaxy techniques to grow the infrared sensitive HgCdTe material. The spectral response for HgCdTe focal plane arrays typically used in astronomy ranges from from 0.8 μm to 2.4 μm. The backside illuminated material is connected to multiplexers of different formats (e.g. 1024×1024 pixels). For arrays that use InSb as a detector material the spectral response goes from 0.5 to 5.4 μm. Typical pixel sizes range between about 10 and 40 μm. About 60% to 80% of all incident photons are detected. Very low dark current and low read noise values make these arrays suited for long exposures under low-background conditions as realized in most astronomical applications. On the other hand, frame rates of above 10 Hz can be reached as well. A similarly high potential for low-background observations in the MIR have BIB (blocked impurity band) detectors.

Focal plane array detectors have also been used in the FIR. A 5×5 array of stressed Ge:Ga photoconductors was flown on the KAO in an imaging spectrometer. Such arrays have also successfully been operated in space (ISO-LWS and ISOPHOT, see below). Larger-format arrays will soon be used on SRTF (Space Infrared Telescope Facility) and FIRST (Far-Infrared and Submillimeter Telescope) and SOFIA. The wavelength range between approximately 80 and 210 μm can be covered with spectral resolutions ($R=\lambda/\Delta\lambda$) of the order of a few thousand.

In the submillimeter and FIR domain ^{3}He-cooled bolometers can be used to perform sensitive measurements of cold dust and faint continuum sources in general (e.g. SCUBA: Submillimetre Common-User Bolometer Array at the JCMT and the IRAM bolometer arrays). Heterodyne receivers for low-noise high-spectral-resolution measurements in the submillimeter range employ Schottky diodes (semiconductor–metal contacts) and SIS diodes (supraconductor/insulator/supraconductor tunneling contacts).

Physical mechanisms

The most prominent infrared continuum radiation mechanism in astrophysical sources is the BLACK-BODY RADIATION that follows a Planck law (see below). This radiation is emitted by all bodies, from dust to planets and stars, and peaks for temperatures below a few thousand kelvin in the infrared. For the ambient temperature of about 300 K the spectral peak is at a wavelength of 10 μm. Other important continuum radiation mechanisms are the free–free and synchrotron radiation emitted by thermal and relativistic plasmas respectively, in or near star-forming regions in our own galaxy and in the nuclei of Seyfert galaxies and quasars. The line emission is dominated by rotational lines in the millimeter and submillimeter domain, fine structure lines of atoms and ions in the FIR and rotational vibrational as well as recombination lines in the MIR and NIR domain. Due to large variations of optical depths and large column densities of emitting and absorbing material, radiative transport of energy is of special interest for both continuum and line radiation (e.g. Osterbrock 1974, Spitzer 1978).

Radiative transport

In a plane-parallel cloud, radiative transport at a frequency ν can be treated simply. The change of specific line intensity I_ν (erg s^{-1} cm^{-2} Hz^{-1} sr^{-1}) along an infinitesimal element dz along the line of sight through a molecular cloud is given by:

$$\frac{\mathrm{d}I_\nu}{\mathrm{d}z}=\frac{h\nu}{4\pi}n_u A_{ul}-\frac{h\nu}{4\pi}\Phi(\nu)I_\nu(n_u B_{ul}-n_l B_{lu})=\epsilon_\nu-\kappa_\nu I_\nu. \quad (1)$$

Here n_u, n_l are the volume densities of molecules in the upper and lower states of the transition, with the corresponding statistical weights g_u and g_l. The Einstein coefficient A_{ul} (s^{-1}) is the rate of decay of n_u by spontaneous radiative transitions. The line shape is described by $\Phi(\nu)$, normalized to $\int\Phi(\nu)\,\mathrm{d}\nu=1$. The volume emissivity and absorption coefficient are denoted by ϵ_ν and κ_ν. With these coefficients the sources function Σ_ν can be defined that is equivalent to Planck black-body radiation law and is the most important source function for electromagnetic radiation in the infrared:

$$\Sigma_\nu=\frac{\epsilon_\nu}{\kappa_\nu}=\frac{2h\nu^3}{c^2}\frac{1}{\exp(\frac{h\nu}{kT_{\mathrm{ex}}})-1}. \quad (2)$$

This gives the spectral energy density of a black-body as a function of the excitation temperature T_{ex}

(an equivalent Planck temperature) that describes the population of states l and u through a thermal Boltzmann population. Using Σ_ν and an optical depth through the cloud $\tau_\nu = -\int_0^z \kappa_\nu \, dz$ the radiative transport equation from above can be simplified to:

$$I_{\nu,\text{observed}} = I_{\nu,\text{background}} \, e^{-\tau_\nu} + \Sigma_\nu (1 - e^{-\tau_\nu}). \quad (3)$$

This equation shows that the absorption in a molecular cloud is proportional to $e^{-\tau_\nu}$ and the emission proportional to $(1 - e^{-\tau_\nu})$.

Line emission

Besides recombination lines of hydrogen and helium the IR exhibits a broad variety of fine structure lines from atoms and ions and rotational and vibrational lines of molecules. The line emission in the submillimeter and long-wavelength FIR is dominated by rotational transitions of simple diatomic and linear multiatomic molecules. They have a simple ladder of rotational energy states E_J depending on the rotational quantum number J and the rotational constant B(Hz) as (to first order):

$$E_J = hBJ(J+1). \quad (4)$$

Electric dipole transitions in molecules with permanent electric dipole moments occur at a frequency $\nu_J = 2BJ$. The maximum emission in the ladder populated at a temperature T_{rot} occurs approximately at $E_J = hBJ(J+1) \approx kT_{\text{rot}}$, or $J_{\max} \approx \sqrt{(kT_{\text{rot}})/(hB)}$. One of the most important molecules for millimeter and infrared astronomy is carbon monoxide (CO) with its lowest $J = 1$–0 rotational transition at 115 GHz (2.6 mm wavelength). In the submillimeter and FIR higher rotational transitions from warm (30 to 100 K) and hot (several 100 K) molecular gas can be observed. These transitions are excited via collisions of CO with H_2 molecules. The dipole line radiation of CO therefore indirectly traces the spatial distribution, density and temperature of molecular gas. Only a small fraction (in star-forming regions of entire galaxies typically one part in a million or less) of very hot molecular gas (a few 1000 K) can be observed via quadrupole radiation in ro(tational)-vibrational NIR lines from the H_2 molecule.

In case of ro-vibrational transitions of linear molecules that occur in the NIR domain the energy states are labeled by the vibrational (v) and rotational (J) quantum numbers

$$E(v, J) = \frac{h}{2\pi}\omega_0 \left(v + \frac{1}{2}\right) + hBJ(J+1). \quad (5)$$

The correction terms are due to centrifugal stretching and Coriolis coupling of the rotational and vibrational motions. The ro-vibrational lines in electric dipole transitions with $v \rightarrow v - 1$ and $J \rightarrow J \pm 1$ can be approximated via

$$\nu_{v,J\rightarrow J\pm1} = \omega_0 \pm 2hBJ(J+1). \quad (6)$$

An important band head of ro-vibrational CO line absorption is found in ~3000 K atmospheres of late-type stars in the NIR at a wavelength of 2.31 μm. It is used for instance to analyse stellar populations and kinematics in the nuclei of galaxies.

The line emission in the MIR and FIR is dominated by fine structure line transitions. In the optical thin limit the integrated line flux (erg s^{-1} cm^{-2}) of a fine structure line can be written as:

$$F_{\text{line}} = \frac{h\nu}{4\pi} \int_{\text{Beam}} \int_{\text{LOS}} n_u \, dl \, d\Omega. \quad (7)$$

Here LOS is the line of sight and $d\Omega$ the differential solid angle used to integrate the line emission over the telescope beam. An important fine structure line is the [CII] line at a wavelength of 158 μm. It is one of the brightest cooling lines of the interstellar medium and can contain up to almost 1% of the overall infrared luminosity of an entire galaxy. In figure 1 the infrared spectrum of the starburst galaxy M82 is shown.

Space missions

In the following some of the recent larger INFRARED SPACE MISSIONS are summarized briefly, both in terms of their technical definitions and scientific results.

IRAS

IRAS was launched on 25 January in 1983 with a telescope mounted in a liquid helium cooled cryostat. The telescope was a Ritchey–Chrétien design with a 0.57 m aperture. The mirrors were made of beryllium and cooled to approximately 4 K. During its 10 months of operation, and in addition to numerous pointed observations, IRAS surveyed more than 96% of the sky up to four times at four infrared bands centered at wavelengths of 12, 25, 60 and 100 μm with its detectors cooled to 3 K. The survey array consisted of 62 rectangular infrared detectors arranged in staggered rows such that any real point source crossing the focal plane as the satellite scanned the sky would be seen by at least two detectors in each wavelength band. The survey covered the sky in overlapping strips as the satellite was orbiting in its near-polar orbit, which precessed by about a degree each day. During some pointed observations, individual sources were mapped simultaneously at 50 and 100 μm using a cold internal chopper for flux reference. IRAS also contained a low-resolution spectrometer, which produced a relevant spectral atlas.

With 350 000 detected objects the IRAS mission increased the number of cataloged astronomical sources by almost 70% and has had a major impact on almost every area of astronomy. IRAS extended our knowledge on the evolution of external galaxies. The instruments on board the satellite detected ~75 000 starburst galaxies—galaxies which are extremely bright in the infrared due to their intense star formation. Many of these starburst galaxies showed signs of interaction with companion galaxies and have 'super winds' (galactic scale gaseous outflows) emerging from their centers due to the large number of supernova explosions which occur in these galaxies.

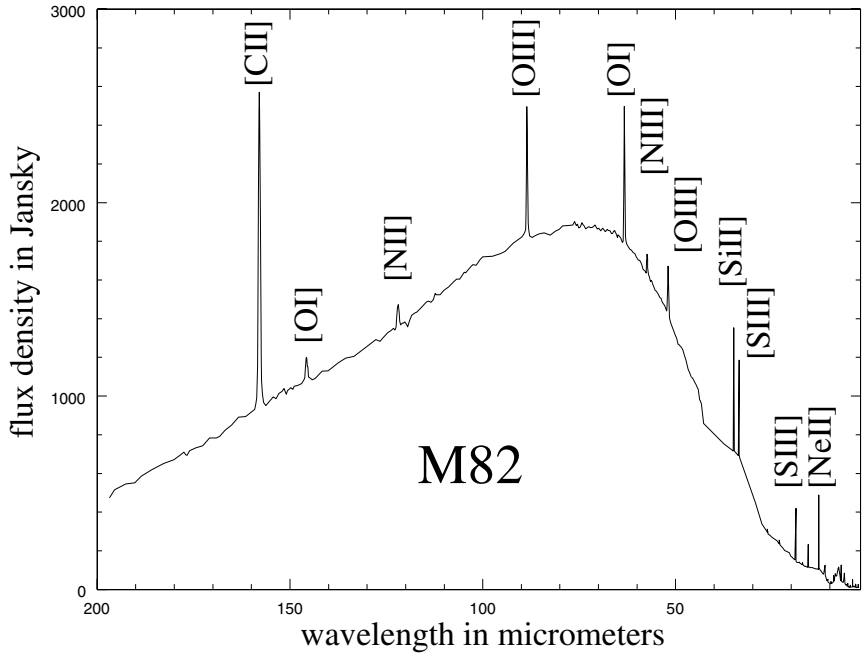

Figure 1. The infrared spectrum of the starburst galaxy M82 as taken with the ISO SWS and LWS spectrometer. In addition to the peak in the dust continuum emission, strong fine structure lines are indicated.

IRAS also found for the first time infrared cirrus: warm dust associated with diffuse clouds mostly at large galactic latitudes. IRAS discovered six new comets and found that comets in general are dustier than previously thought. The FIR observations provided evidence of zodiacal dust bands around other stars (e.g. Vega), and detected several probable protostars embedded in clouds of gas and dust.

ISO

The Infrared Space Observatory (ISO), (see figure 2) (Kessler *et al* 1996) of the European Space Agency (ESA) was an astronomical satellite, operating at wavelengths from 2.5–240 μm. Essentially, ISO consisted of a large cryostat which contained at launch about 2300 l of superfluid helium to maintain the Ritchey–Chrétien 60 cm diameter telescope, the scientific instruments and the optical baffles at temperatures of 2–8 K. ISO was launched by an Ariane 4 on 17 November 1995 and kept in operation for 29 months. The satellite spent roughly 16 h per day outside the radiation belts and during this time the sensitive FIR detectors could be operated. The four focal plane instruments on board ISO consisted of one short- and one long-wavelength spectrograph (SWS and LWS) and imaging experiments in the MIR (ISOCAM) and FIR (ISOPHOT) domain.

The SWS instrument consisted of two grating spectrometers, together covering the wavelength range between 2.38 and 45.2 μm. The overall spectral resolution covered a range of $R = 1000$ (300 km s^{-1}) to $R = 30\,000$ (10 km s^{-1}) by inserting Fabry–Pérot (FP) filters. In its grating mode, the LWS operated from 45 μm to 180 μm with a resolving power between a few 100 and 10 000 using FPs. The ISOCAM infrared imaging camera used

two 32 × 32 pixel detectors, one devoted to the 2.5–5 μm range and the other to the 4–17 μm range. Images in direct and polarized light at several spatial resolutions through a variety of spectral filters could be taken. ISOPHOT was an imaging photopolarimeter for the wavelength range 2.5 to 240 μm and included a low-resolution spectrometer for the 2.5 to 12 μm range.

ISO observations resulted in the first measurements of the lowest rotational transition of molecular hydrogen H_2 at 28.1 μm which is important in determining the distribution and abundance of cold molecular material directly. ISOCAM observations determined the distribution of warm dust near star-formation regions in external galaxies. Via 200 μm imaging, ISO detected 5 to 10 times more 15 to 21 K cold dust than IRAS. LWS and SWS observations of luminous galaxies allowed the determination of the relative contribution of starburst and non-thermal activity in their nuclei.

COBE

The COBE satellite was developed by NASA's GODDARD SPACE FLIGHT CENTER to measure the diffuse infrared and microwave 2.7 K cosmic background radiation from the early universe (due to the Big Bang). It was launched on 18 November 1989 and carried three instruments, a far-infrared absolute spectrophotometer (FIRAS) to compare the spectrum of the microwave background with that of a black-body, a differential microwave radiometer (DMR) to map the cosmic radiation sensitively, and a diffuse infrared background experiment (DIRBE) to search for the cosmic infrared background radiation. The cosmic microwave background spectrum was measured with a precision of 0.005%; for the first time the background was found to have an intrinsic anisotropy, at a level of 1 part in 100 000. Absolute sky brightness maps from 1.25 μm to 240 μm were obtained and the background radiation was detected in the two longest DIRBE wavelength bands at 140 and 240 μm wavelengths.

NICMOS

NICMOS (near-infrared camera and multiobject spectrometer) was an instrument which has been installed in the HUBBLE SPACE TELESCOPE (HST) in orbit and allowed it to observe in the near-infrared. The camera was a second-generation Hubble instrument installed aboard the satellite during a servicing mission in February 1997. NICMOS provided the capability of both imaging and spectroscopy at wavelengths between 0.8 and 2.5 μm. NICMOS contained three cameras designed for simultaneous operation. The optics presented the detectors with three adjacent, but not spatially contiguous, fields of view of different image scales. NICMOS employ three low-noise, high-quantum-efficiency, HgCdTe 256 × 256 element focal plane arrays in a passive dewar using solid nitrogen as a coolant. The camera contained a variety of filters, grisms (a combination of a grid and a prism to allow for dispersion on the optical axis) and polarizers selected through three independent filter wheel mechanisms. Slitless imaging spectroscopy in the widest field camera provided a multiobject spectrographic capability with a resolution of ∼200. NICMOS achieved diffraction-limited performance at 1.0 and 1.75 μm.

Sensitive near-infrared images have been obtained of solar system planets, the central regions of nearby galaxies with ACTIVE GALACTIC NUCLEI (AGN)—like the nearest radio galaxy Centaurus A—or violent star formation activity as in Arp 220. NICMOS also provided a detailed stellar census of the stars in obscured or embedded star clusters like the ORION NEBULA and the galactic center. A comparison of long exposures taken toward selected regions of the so-called HUBBLE DEEP FIELD (HDF) allowed us to improve our knowledge on the spectral energy distribution of the most distant galaxies in the universe.

Sources

In general, dust-embedded sources or dense molecular clouds heated by stars or active galactic nuclei are most luminous in line and continuum radiation in the infrared. In galaxies the luminosity is concentrated toward the nuclei and some active star-forming regions mostly within spiral arms or in barred spirals at the tips of the bars. Ultraluminous galaxies belong to the most luminous objects in the universe and can exhibit more than 10^{12} (a million million) solar luminosities in the infrared. As typical examples of infrared bright objects the nuclear region of the Milky Way (the galactic center), ultraluminous galaxies and star-forming regions are discussed in the following.

Galactic center

Photospheric emission of stars in the galactic center at a distance of 8 kpc (26 400 light years; one parsec (1 pc) equals 3.3 light years) can only be observed in the near-infrared. The visible light from the central stellar cluster is obscured by about 30 magnitudes (one magnitude is a factor of 2.5 in intensity) due to the dust and gas in the galactic plane. High angular resolution, near-infrared imaging and spectroscopy have made it possible in the last few years to measure stellar proper motion and radial velocities in the galactic center down to separations of less than five light days from the compact radio source SgrA* (in the constellation Sagittarius) at the dynamic center of the Milky Way (Eckart and Genzel 1997, Genzel *et al* 1997, Ghez *et al* 1999). These measurements make a compelling case for the presence of a compact, central dark mass of 2.6×10^6 solar masses which is most likely in the form of a supermassive black hole.

The first indications for a central mass concentration in the Milky Way (for a summary see Genzel *et al* 1994) emerged in the late 1970s from spectroscopic observations of a mid-infrared fine-structure line of Ne^+. As radio interferometric observations had discovered a compact, non-thermal radio source, SgrA*, in the same region, a plausible interpretation—by analogy to quasars—was that the large gas velocities indicate orbital motions in the vicinity of a million solar mass black hole, coincident with SgrA*.

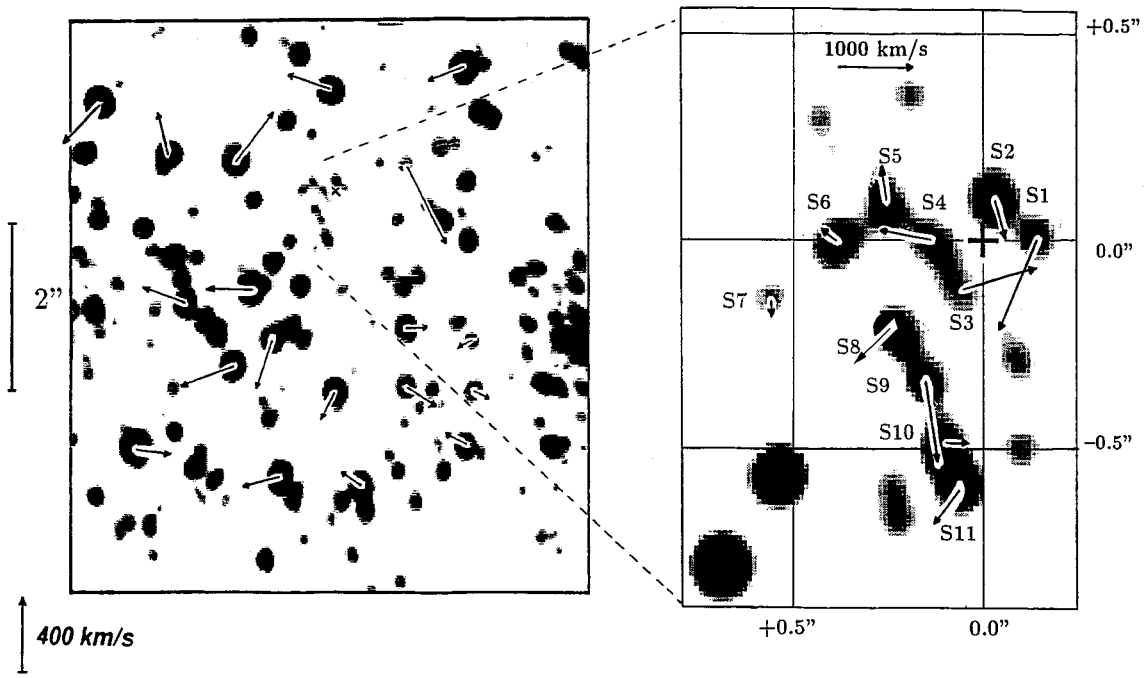

Figure 3. Proper motion vectors of the central sources close to Sgr A* at the galactic center.

In the following years further infrared (and radio) spectroscopic data including radial velocities of stars strengthened the gas dynamic evidence for a dark 1 to 3×10^6 $M_\odot$ central mass. Speckle interferometry revealed a compact 1″ diameter cluster of stars at the position of Sgr A*. Several of these stars in this so-called SgrA* cluster show proper motions in excess of 1000 km s^{-1} (see figure 3). The analysis shows that the projected velocity dispersion of stars increases towards the center as expected in the potential of a large central point mass (a 'Kepler law'). The location of the largest stellar velocities (the dynamic center), the stellar density maximum and the position of SgrA* all agree to within ±0.004 pc. The final distribution of enclosed mass as a function of true radial separation from SgrA* is shown in figure 5 of the article on SUPERMASSIVE BLACK HOLES IN INACTIVE GALAXIES. Simple physical considerations show that this central object with such a high mass and density cannot be stable and must be present in the form of a supermassive black hole. Together with the nucleus of NGC4258 (Greenhill *et al* 1995, Myoshi *et al* 1995)—in which very long baseline radio interferometric observations discovered a rapidly rotation circumnuclear disk—the galactic center currently is the very best case for a supermassive black hole.

Ultraluminous infrared galaxies

The extragalactic infrared background radiation and the identification of individual FIR galaxies (results from COBE, ISO, SCUBA) is starting to tell the history of star formation in the early universe. The IRAS satellite discovered a class of ultraluminous infrared galaxies which have the luminosity of quasars and show obvious signs of nuclear activity and advanced tidal interactions (Sanders *et al* 1988). Ultraluminous infrared galaxies (ULIRG) represent an important stage in the evolution of a wide variety of extragalactic objects including powerful nuclear starbursts, radio galaxies and quasars. They may also represent a primary stage in the formation of elliptical galaxy cores via the merger of two gas-rich spirals. ISO could contribute significantly to the investigation of ULIRGs. The ISO SWS and ISOPHOT mid-infrared spectroscopic survey of ULIRGs showed that 70–80% of them are predominantly powered by recently formed massive stars (Genzel *et al* 1998). However, about 20–30% are powered by a central AGN. These conclusions are based on an infrared 'diagnostic diagram' involving the ratio of high- to low-excitation mid-IR emission lines and the strength of the 7.7 μm PAH (polycyclic aromatic hydrocarbon) feature. At least half of the sources probably have simultaneously an active nucleus and recent or on-going starburst activity in a 1–2 kpc diameter circumnuclear disk or ring. No obvious trend for the AGN component to dominate the most compact, and thus most advanced, mergers was found. Instead, at any given time during the merger evolution, the time-dependent compression of the circumnuclear interstellar gas, the accretion rate onto the central black hole and the associated radiation efficiency may determine whether star formation or AGN activity dominates the luminosity of the system.

Star formation process

The investigation of the star-formation process profits significantly from infrared and submillimeter observations (Beckwith and Sargent 1996). Although the solid particles probably make up no more than about 1% of the disk mass they produce almost 100% of the radiation between 2 μm and $\sim$1 mm wavelength. The range of strong emission from the NIR to the radio is the result of a wide variation of temperatures, from $\sim$1000 K very close to the stars to $\sim$30 K near the outer edge of the disk at several hundred AU distance from the center. This makes it relatively easy to find disks at infrared wavelengths. The silhouettes of these disks are seen by the HST against the bright background of the Orion nebula. They show flattened, elliptical shapes and demonstrate for the first time that disks are truncated sharply at their outer radii.

Disks are very common surrounding many young stars. Half of the classical T Tauri-type stars in the Taurus–Auriga and Ophiuchus dark clouds show evidence for disks. An important new finding is that disks are common in dense clusters of young stars such as at the center of the Orion nebula (Lada *et al* 1993).

In general one discriminates between four stages of star formation (Shu *et al* 1987): first dense cores form in molecular clouds while magnetic and turbulent support is lost through diffusion of neutral particles. Then a protostar with a surrounding nuclear disk is formed via a collapse of the dense cores from inside out. Following this stage a stellar wind breaks out along the rotational axis of the system and creats a bipolar outflow. Finally the infall is terminated and a young star with a circumstellar disk is revealed.

Star-forming regions

Infrared observations are especially well suited for observations of gas clouds in active star-forming regions within our own galaxy such as the Trapezium region in the Orion nebula, M17 or M49 (see e.g. Yun and Liseau 1998). The UV radiation of clusters of recently formed O- and B-stars interacts in so-called photon-dominated regions (PDR) with the surrounding dense molecular gas at a distance of only a fraction of a parsec. By heating the gas, about 0.5% of the strong UV radiation is converted into bright infrared line emission. The investigation of these lines allows us to determine the density and temperature structure as well as abundances and chemical processes in these interface regions.

The ISO SWS observations allowed detailed investigations of interstellar ices and for the first time an unbiased overview of their compositions. The results include observations of solid CO_2, solid CH_4 and HCOOH. In the gas phase important information has been obtained on the abundance of water in warm star-forming regions, through the study of rotation vibrational lines with SWS and pure rotational lines with LWS. The gas to solid state ratios are important for investigations of the gas-grain chemistry in dense clouds in star-forming regions.

Infrared Astronomy Satellite

The Infrared Astronomical Satellite (IRAS), a collaboration between the United States, the United Kingdom and the Netherlands, was the first space mission aimed at a systematic all-sky survey at infrared wavelengths inaccessible from the ground. IRAS surveyed more than 96% of the sky at 12, 25, 60 and 100 μm (micrometers) with unprecedented sensitivity, revolutionized INFRARED ASTRONOMY and made significant contributions to almost every area of astrophysical research from solar system studies to cosmology.

The IRAS telescope (figure 1, made of beryllium, had a 57 cm primary mirror and was kept at about 4 K inside a cryostat cooled by liquid helium. The focal plane of the telescope carried 62 detectors, divided about equally among the four survey wavelengths, and arranged in a staggered array to collect data for the all-sky survey as the telescope scanned the sky. The detectors subtended from 0.5 to 5 arcminutes each on the sky and allowed detections down to 0.1–1 Jy depending on wavelength. The focal plane also carried a Low Resolution Spectrometer (LRS) covering from 7.5 to 23 μm with a spectral resolution of about 20 and a Chopped Photometric Channel (CPC) with one detector at each of 50 and 100 μm, as well as visible star sensors used for pointing information.

IRAS was launched on 25 January 1983 into a 900 km, 103 min Earth orbit which remained in a plane nearly normal to the Earth–Sun line. As the satellite traveled on its Sun-synchronous orbit, the telescope pointed away from the Earth and scanned methodically so the image of the sky traveled across the focal plane, and sources were sensed by the detectors. The resulting data were calibrated and processed at IPAC to catalog over 370000 infrared sources and to generate all-sky images at a resolution of a few arcminutes and spectra of almost 3000 infrared sources (see figure 2). Part of the mission was also used to conduct deeper observations of preselected targets (see figure 3). The IRAS cryostat ran out of helium in November 1983, rendering the focal plane useless and ending the mission.

IRAS detected six new comets, measured the emission from 2000 asteroids and discovered the zodiacal dust bands which trace the dust generated in collisions among asteroids. IRAS also detected more infrared emission from stars than could be attributed to the stars themselves, evidence of dust around those stars analogous to zodiacal dust around the Sun and potentially an indica-

tion of planetary systems; VEGA and BETA PICTORIS are especially well-studied cases. IRAS mapped in detail the density and temperature in molecular clouds where stars form, revealed their full energy balance and found thousands of cores hosting protostars. IRAS revealed a full view of the bulge of the Milky Way and discovered diffuse infrared emission from dust in our galaxy, bright and warm towards the plane and wispy and cold above the plane, hence the name 'infrared cirrus'. Cirrus emission is a valuable source of information on the interstellar medium and a potential impediment to infrared source measurement in certain lines of sight. It was used to estimate the amount of visible light extinction by dust for each direction on the sky and to find the best windows for observing outside the Milky Way at all wavelengths.

IRAS detected a total of 75 000 galaxies and quasars whereas less than a hundred had been observed as infrared sources before. This was the first truly unbiased, unobscured survey of extragalactic objects, allowing for the analysis of their infrared colors, of their distribution in space and of their evolution over the past few billion years. IRAS discovered a new class of galaxies with tens of times more luminosity emerging in the infrared than in the visible and with overall luminosities comparable with quasars. These 'ultraluminous infrared galaxies' arise most often from collisions or mergers between normal disk galaxies and may turn into quasars after the infrared-emitting dust has dissipated; Arp 220 and IRAS F10214+4724 are especially well studied cases. At lower luminosities, IRAS data allowed detailed analysis of the STARBURST phenomenon, due to intense star formation in extremely dense gas at the centers of galaxies. IRAS has also made certain types of objects famous, for example Arp220 and F10214.

G. Helou

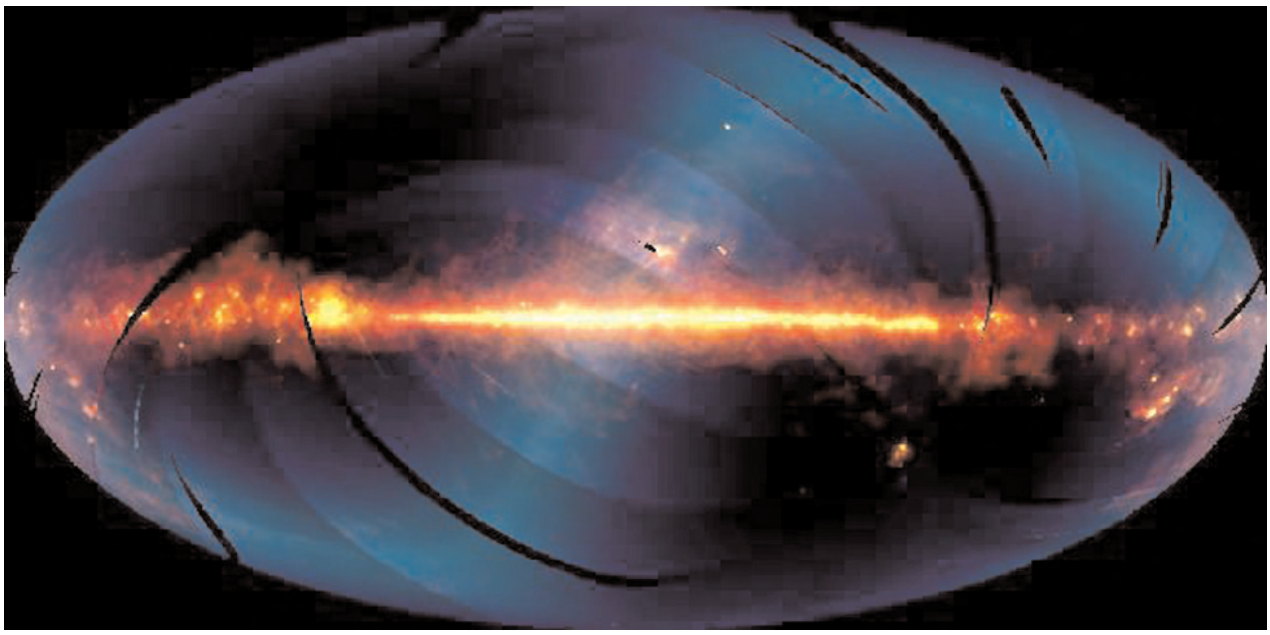

Figure 2. Nearly the entire sky, as seen in infrared wavelengths and projected at 0.5° resolution, is shown in this image, assembled from 6 months of data from IRAS. The bright horizontal band is the plane of the Milky Way, with the center of the Galaxy located at the center of the picture. The colors represent infrared emission detected in three of the telescope's four wavelength bands (blue is 12 μm; green is 60 μm and red is 100 μm). Hotter material appears blue or white while the cooler material appears red. The hazy, horizontal S-shaped feature that crosses the image is faint heat emitted by dust in the plane of the solar system. Celestial objects visible in the photograph are regions of star formation in the constellation Ophiucus (directly above the galactic center) and Orion (the two brightest spots below the plane, far right). The Large Magellanic Cloud is the relatively isolated spot located below the plane, right of center. Black stripes are regions of the sky that were not scanned by the telescope in its first six months of operation. Credit: IPAC, Caltech/JPL.

Infrared Imagers

In contrast to visual observations at wavelengths of 0.35–0.7 μm with their long history of astronomical discoveries, the only celestial source detectable in the infrared region ($\lambda > 1$ μm) by unaided human senses is the Sun. Consequently, the development of INFRARED ASTRONOMY had to wait for technical detection methods. The existence of infrared radiation was first demonstrated by Herschel, using thermometers to show that energy is being received in the invisible parts of the solar spectrum. Sophisticated versions of thermometers, so-called bolometers, are still the detector of choice at very long (submillimeter) wavelengths. At shorter infrared wavelengths, photon-detecting semiconductor detectors became available shortly after WWII. Detector systems built around these devices were only single-point photometers, and spatial images had to be obtained by sequentially measuring the signal at each position in the image. The first true infrared imagers were built in the 1980s when INFRARED ARRAYS became available for astronomy.

Problems of ground-based infrared observations

Several factors combine to make ground-based infrared observations more difficult than observations in the optical (0.3–1.0 μm) region. While the atmosphere in the optical is of uniformly high transmission, the infrared region is subdivided into windows of atmospheric transmission, separated by spectral bands where absorption by atmospheric trace gases such as CO_2 and H_2O renders the atmosphere opaque. Since the water vapor content of the atmosphere strongly depends on the climatic conditions and since the scale height of water in the atmosphere is small, infrared astronomical observations are best carried out from dry, high-altitude sites.

Ambient temperature ($T \approx 300$ K) surfaces emit copious photons at wavelengths longer than about 2 μm. Therefore, the emissivity (e) of the telescope optics must be minimized to reduce the photon background contributed by the telescope itself. While high reflectivity (r) of the mirrors, and thereby low emissivity ($e = 1-r$), is desirable for any telescope, high emissivity reduces the signal-to-noise ratio in the infrared much faster than poor reflectivity does in the optical. Dedicated INFRARED TELESCOPES are designed to minimize the area of obstructions by black, highly emitting surfaces in the lightpath (e.g. secondary support spiders, the secondary mirror mount and the hole in the primary mirror). The technologies have been developed to coat at least the secondary mirror, if not also the primary, with silver, to significantly reduce the emissivity compared with the more traditional aluminum coatings.

Infrared detectors are sensitive to the radiation emitted by ambient temperature surfaces. Simply enclosing the detector with black surfaces does therefore not eliminate the background radiation. In addition to cooling the detector itself to its operating temperature, an infrared camera requires all surfaces surrounding the detector, including the optics, to be cooled, using liquid cryogens such as liquid nitrogen or liquid helium, or by closed-cycle cooler systems. As a consequence, infrared astronomical instruments tend to be far more complicated and costly than their optical counterparts.

The design of infrared imagers

Various optical designs are possible for an infrared imager. The choice of a specific design is driven by the requirements of field of view, pixel scale, image quality, throughput and wavelength range as scientific criteria, but also by budget and schedule considerations. Further, a distinction is often made between investigator-class instruments, which are designed to primarily serve the specific scientific interest of their designer, and facility instruments, which are intended to serve a wide user community for a variety of scientific projects. Facility instruments typically offer a larger number of operating modes, have more elaborate software to allow occasional users to operate them efficiently, are generally built to higher standards of reliability and serviceability, and are better documented. Not surprisingly, they also tend to be far more expensive than investigator-class instruments and take much longer to design and build.

A specific example

Figure 1 illustrates the very basic elements of a simple infrared imager design and shows the optical path for three field points. Figure 2 gives more details of the specific technical implementation chosen for the Quick Infrared Camera (QUIRC) built at the University of Hawaii for their 2.2 m telescope. When this camera was built in 1994, it was the first to use a detector array of 1024×1024 format.

A dewar window of infrared-grade fused silica seals the inside of the cryostat and allows it to be evacuated in preparation for cooling of the interior components of the infrared camera with liquid nitrogen. The dewar window is the last optical element of an infrared camera that remains at ambient temperature. Therefore, its emissivity must be kept low and scattering of thermal radiation into the lightpath of the camera must be minimized. These requirements dictate the choice of a high-transmission material and good surface polish.

The first cooled optical element is a field lens located in or close to the focal plane of the telescope. The field lens produces an image of the telescope pupil, which is the optical surface defining the aperture of the telescope. Many infrared telescopes are designed with undersized secondary mirrors, making the secondary the pupil in the system. However, the UH 2.2 m telescope is a classic optical wide-field telescope, so the $f/10$ secondary mirror is oversized and therefore the primary mirror is the pupil of the telescope. The field lens thus produces an image of the telescope primary, seen reflected in the secondary mirror, on a surface inside the cryostat where a cold stop can be placed. Since a field lens is located close to the focal plane of the telescope its optical aberrations do not

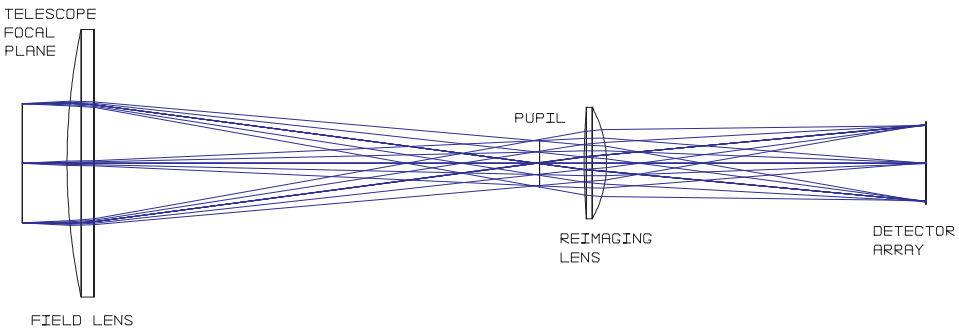

Figure 1. Basic elements of a simple infrared imager design.

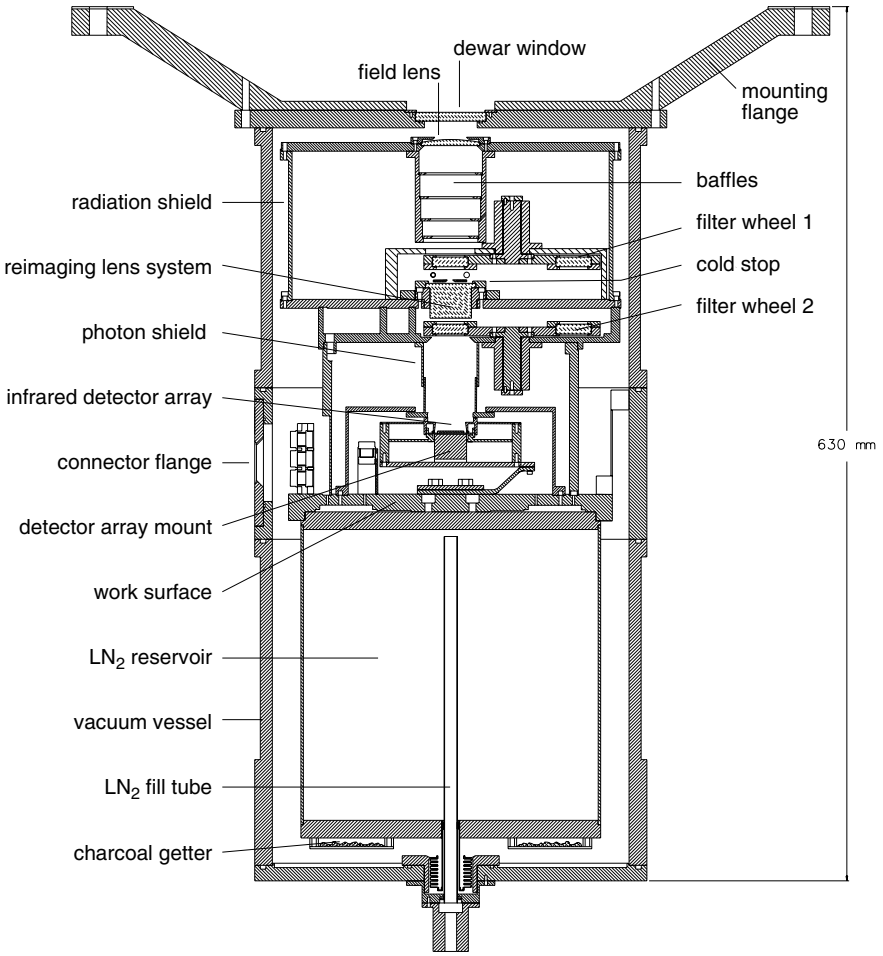

Figure 2. Infrared imager implementation for QUIRC.

significantly affect the image formed on the detector. Field lens aberrations do, however, affect the quality of the pupil image and thereby our ability to mask off unwanted thermal radiation. In a simple camera like QUIRC, the field lens is usually a single spherical lens made of a high refractive index material (ZnSe or ZnS), so that spherical aberration is minimized. A better, but more expensive, solution would be to use an aspheric lens.

The next important element is the pupil cold stop. Its purpose is to block all radiation that does not come from the telescope pupil (the primary mirror in our case) from reaching the detector. In particular, radiation coming from the mirror mount just outside of the mirror's reflective surface and radiation emitted by the central hole in the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Cassegrain primary mirror must be blocked. The cold stops are typically designed as an aperture slightly smaller than the pupil image, with a central occulting disk masking the image of the hole in the primary. The central occulting disk is usually suspended by wires that also act to mask the support 'spider' arms holding the telescope secondary mirror. By undersizing the hole in the cold stop, the cold stop effectively becomes the pupil of the combined telescope and camera system.

Infrared imagers use interference filters to select the spectral region of interest. Usually one or more filter wheels are located near the pupil stop of the optical system. When placed near the pupil (figure 1), light from all field points passes through the same area of the filter so that non-uniformities in the filter affect all objects in the field in the same way and can therefore be more easily corrected.

The main optics of the infrared camera are located just behind the pupil stop. Their purpose is to reimage the telescope focal plane onto the detector array. By choosing the focal length and the distances, these reimaging optics can be used to magnify or demagnify the original focal plane image, depending on the desired pixel scale. Usually, combinations of two or more lens materials are used to correct chromatic aberrations. For example combinations of BaF_2 and Schott SF6 glass work well in the near infrared, while combinations of BaF_2 and LiF, sometimes combined with other, higher-index materials such as ZnS and ZnSe work well at wavelengths out to 5.5 μm.

The final and most important element in the infrared camera is the focal plane detector array that collects the photons and allows the signal to be measured. Detector arrays of up to 1024 $\times$ 1024 pixels are now available for near-infrared observations (1.0–5.5 μm) and arrays in 2048 $\times$ 2048 format are under development. Infrared arrays for mid-infrared wavelengths typically have smaller formats (see MID-INFRARED INSTRUMENTATION).

The refractive optical design outlined above is by no means the only possible solution. Purely reflective designs have been developed, in particular for mid-infrared cameras where the choice of suitable refractive materials is even more restricted than in the near infrared. One particular, surprisingly simple reflective design is the Offner relay (figure 3), consisting of a large, concave spherical mirror and a small, convex spherical mirror of double the curvature of the large mirror. The two mirrors are mounted concentrically. In this configuration, the Offner relay reimages the focal plane of the telescope onto the detector while forming a pupil image on the small secondary mirror. This simple optical arrangement is free of all first-order aberrations and offers high throughput, but it is limited to exactly reproducing the image scale in the telescope focal plane. Further, the quality of the pupil image is not very good, but can be corrected with additional optical elements.

Additional capabilities

Most infrared imagers, in particular facility-class instruments, include additional optical elements to expand their capabilities beyond pure imaging.

Polarimetry

Infrared imaging polarimeters usually use a fixed, cooled analyser in the instrument and rotate the polarization plane by an external warm rotatable half-wave plate that emits very little thermal radiation owing to its low emissivity. Wire-grid analysers transmit one polarization plane and absorb the other. Their advantage is that they can be used in the same way as filters, and therefore allow the implementation of polarimetric capability at very low system cost. Beamsplitting elements such as Wollaston prisms split the light into two orthogonal polarization planes, allowing the simultaneous detection of both planes as two separate images of the object. This is obviously a more efficient use of the photons coming from the object and has the added advantage that any instabilities in the atmospheric transmission during the exposure time affect both polarization planes in the same way, making the observation immune to such atmospheric effects. The disadvantage is that Wollaston prisms require a collimated light path and thus dictate a slightly more complex optical design.

Spectroscopy

Spectroscopic capability can be implemented in an infrared imager by using a grism (an integrated grating and prism combination) in a collimated light path near the pupil of the system. Except for rare slitless use, spectroscopy usually requires a slit to be placed in the focal plane of the telescope.

Coronagraphic observations

A special case of imaging observations are coronagraphic observations. In this context these are not observations of the solar corona but of faint features and objects near bright stars, such as faint binary companions, including brown dwarfs, faint dust-scattering features such as remnants of protoplanetary disks, and faint emission line features associated with stellar jets. What these observations have in common with observations of the solar corona is that careful attention must be paid to reducing the scattered light from the bright central object. Infrared cameras already have a pupil stop (called a Lyot stop in the context of coronagraphs). With the addition of an occulting mask in the telescope focal plane, proper attention to stray light issues in the optical design (avoiding ghost reflections) and potentially the use of special cold stop masks, infrared imagers can become very capable CORONAGRAPHS.

Data reduction

Most near-infrared detector arrays used today provide the option of non-destructive reading, i.e. reading the accumulated image information in the array without destroying this information. After resetting a detector

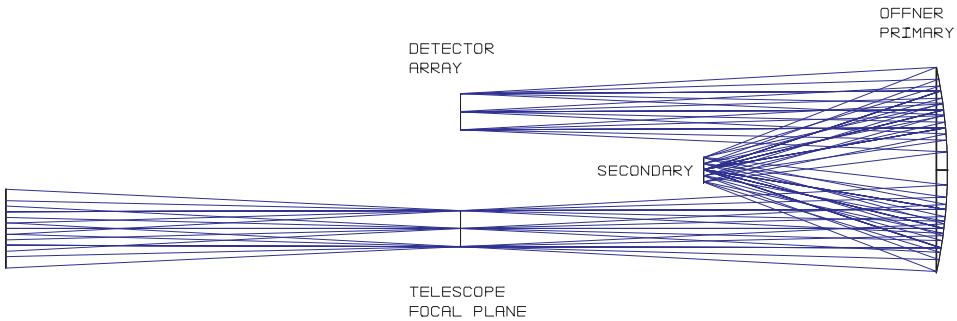

Figure 3. The Offner relay.

array to erase all previous imaging information, a typical double-correlated frame consists of two reads of the detector array: one read at the beginning of the integration time and then one read at the end. The difference of these two reads represents the signal accumulated during the integration time. While this double-correlation technique eliminates many of the artifacts from the detector array and the readout electronics, such a single frame is usually not a useful astronomical image. Two additional steps are required, at minimum, to extract and calibrate the astronomical information.

The first is usually called 'sky subtraction', but it removes more than just uniform background from the sky. For example, a dust particle on the cryostat window emits infrared radiation that is clearly not coming from the sky but is superposed on the astronomical signal. The most straightforward way of subtracting the sky would be to take an exposure of a blank piece of sky close to the object and subtract that from the object frame. While this method was commonly used in the early days of infrared imaging, the sensitivity of today's infrared imagers is so high that there is virtually no place in the sky that is really 'blank', i.e. devoid of detectable objects. Therefore, a sky frame needs to be computed from a large number of images taken at different telescope positions close to and including the position of the object of interest. All features that remain stationary in such a set of images are instrumental artifacts, such as the dust particle on the window discussed earlier. Computing a median through such a stack of frames eliminates all objects that changed their position between exposures, i.e. all astronomical sources, and preserves all stationary features. The resulting 'median sky' can then be subtracted from each frame individually, to remove instrumental artifact emission and sky background from the frames.

The second step is to correct for non-uniformities in the pixel response across the array. One way to measure this so-called 'flat field' is to take images of a uniformly illuminated surface. The inside of a telescope dome, which is quite uniformly painted and out of focus to the telescope, is usually suitable for this calibration measurement. The difference between an exposure of the dome with incandescent lights on and a second exposure with the lights off gives the response of the detector array to radiation of the few thousand kelvin temperature and eliminates artifacts from ambient temperature emission from the telescope optics. A flat 'field frame' obtained this way is then used to divide the individual astronomical frames by correcting the non-uniformities in the detector array. The resulting sky-subtracted and flat-fielded frames are then added together, compensating for the telescope motions between frames to form a 'mosaic' image.

Bibliography

Infrared Space Missions

Infrared radiation occurs at longer wavelengths than visible light, in the region 1–250 μm. Although cosmic near-infrared radiation can penetrate Earth's atmosphere through narrow 'windows', making ground-based observations possible, longer wavelengths are absorbed by the air. Observations at these wavelengths are possible only through space-based observatories.

Preliminary studies using instruments on sounding rockets, the Soviet Salyut 4 space station and the Kuiper Airborne Observatory took place in the 1970s and paved the way for the first infrared sky survey satellite.

The US–Netherlands–UK INFRARED ASTRONOMY SATELLITE (IRAS) was launched into a 900 km Sun-synchronous orbit on 25 January 1983. It carried a Ritchey-Chrétien telescope, with a 57 cm primary mirror, which was cooled to 2 K by liquid helium. During its operational lifetime of 300 days, IRAS surveyed 98% of the sky at 12, 25, 60 and 100 μm. Some 250 000 infrared sources were cataloged as the result of IRAS observations, compared with approximately 5000 previously known sources.

IRAS made many new discoveries within the solar system. Six new comets were found, including IRAS–Araki–Alcock, which passed close to the Earth in May 1983. Among the new asteroid finds was an unusual object, 3200 Phaethon, which may be an extinct comet. IRAS also revealed hitherto unsuspected dust trails associated with comets, as well as a torus of warm dust produced by collisions between Main Belt asteroids and associated with the Zodiacal Light.

Further afield, IRAS discovered that a number of stars, including Vega, which appeared much brighter than expected at infrared wavelengths, were surrounded by dust disks. Astronomers were also able to study cool interstellar dust clouds, newborn stars embedded inside nebulae and some 50 000 distant galaxies.

Infrared observations were made subsequently during two shortlived space missions. A 15 cm infrared telescope was flown on the Spacelab 2 mission (29 July–6 August 1985), but results were disappointing, largely due to high infrared background radiation from the Space Shuttle.

An instrument of similar size, known as the Infrared Telescope in Space, was placed on the Japanese–US Space Flyer Unit, a small orbital platform which was launched by an H-2 rocket on 17 March 1995. It operated for a few weeks until its supply of helium was exhausted, then remained dormant until the other onboard experiments were completed and the satellite could be recovered by the Space Shuttle in January 1996.

An infrared mission of a very different kind operated in the period between these two brief flights. NASA's Cosmic Background Explorer (COBE) carried the Diffuse Infrared Background Experiment, which studied the entire sky at ten wavelengths between 1 and 300 μm. Its 20 cm Gregorian telescope produced some of the best maps ever made of the infrared sky's overall structure, as well as the first map of the cumulative infrared emission from primordial galaxies which formed soon after the the Big Bang.

Also located inside the satellite's helium cryostat was the Far-Infrared Absolute Spectrophotometer, which studied the spectrum of the cosmic background radiation. Two months after launch, researchers announced that the spectrum of the Big Bang's afterglow matched that of a 2.73 K black body.

The true successor to IRAS was the European Space Agency's Infrared Space Observatory (ISO), though its mission was to focus on specific targets rather than carry out an all-sky survey. ISO was launched into a highly elliptical orbit on 17 November 1995.

Much larger than its predecessor, ISO carried a 60 cm Ritchey–Chrétien telescope, four scientific instruments and sufficient helium coolant to operate for 28 months. The camera, photometer and two spectrometers between them covered the full range of infrared wavelengths from 2 to 200 μm.

Data from ISO are still being analysed, but a number of significant initial results have been announced, including the discovery that water is much more widespread throughout the Galaxy than expected. ISO observations show that water is present in the atmospheres of Saturn's moon Titan and the outer planets, in planetary nebulae and in giant molecular clouds. The satellite was also well placed to study the prodigious dust and gas emissions from Comet Hale–Bopp.

The observatory has also revealed the first glows from concentric rings of cold dust in the Andromeda galaxy, the existence of complex organic molecules around young stars, and the first known infrared-bright gravitational arcs. Dozens of distant galaxies which contribute to the Cosmic Infrared Background have been detected.

Two more infrared observatories are currently planned. NASA's SPACE INFRARED TELESCOPE FACILITY (SIRTF) has undergone many changes since it was first proposed in the 1970s. Although its mass has been reduced to about 900 kg, and the amount of liquid helium it will carry is only 360 litres, its mission lifetime requirement remains 2.5 years.

In late 2001 or early 2002, SIRTF will be placed into an Earth-trailing heliocentric orbit which causes it to drift away from Earth at the rate of $\sim$ 0.1 AU per year. This choice of orbit has been preferred over a geocentric orbit for its more benign thermal environment. A 'warm-launch' scenario has also been chosen, whereby SIRTF's telescope assembly is launched at ambient temperature and allowed to cool passively in space. Only the focal-plane instruments and the compact cryostat are enclosed in a vacuum shell, resulting in a dramatic reduction in the volume of liquid helium required. The 85 cm diameter primary mirror is fabricated entirely of beryllium, and the telescope is a Ritchey–Chrétien design.

The Infrared Imaging Surveyor (IRIS)—originally designated as ASTRO-F—is the second infrared astronomy

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

mission of the Japanese Institute of Space and Astronautical Science (ISAS). Scheduled to be launched in February 2003, IRIS will be placed into a Sun-synchronous polar orbit at an altitude of 750 km by the ISAS M-V rocket. It will carry out an infrared sky survey with much better sensitivity than IRAS, and is expected to add significant information on many astrophysical problems such as the evolution of galaxies, formation of stars and planets, and the contribution of brown dwarfs to dark matter.

IRIS has a 70 cm Ritchey-Chrétien type telescope cooled to 6 K with liquid helium and Stirling-cycle coolers. It will carry two focal-plane instruments: a Far-Infrared Surveyor, which will survey the entire sky in the wavelength range from 50 to 200 μm with angular resolutions of 30–50 arcsec; and an Infrared Camera that will take deep images of selected sky regions in the near- and mid-infrared range.

Meanwhile, observational capabilities in the near-infrared will also be enhanced by the launch of the 8 m Next Generation Space Telescope (NGST) in 2007–8. Following on from the successful installation of the Near Infrared Camera and Multi-Object Spectrometer (NICMOS) on the HUBBLE SPACE TELESCOPE in 1997, NASA and ESA are looking towards building an observatory that will detect radiation at wavelengths of 0.6 to 20 μm (optimized for the 1–5 μm region). NGST will enable astronomers to study extremely distant objects whose radiation has been greatly redshifted when observed in the current epoch.

Infrared Telescopes

The infrared region of the spectrum covers a wide range of wavelengths—from 0.7 to 1000 μm. However, astronomers usually restrict the term 'infrared' to the more limited region of 1 to 350 μm—though even this is over 100 times wider than the visible region of the spectrum.

Infrared radiation was discovered in 1800 by William HERSCHEL, during his investigations of the visible light spectrum. When he placed a thermometer outside the red end of the rainbow spectrum, Herschel found that an invisible source of radiation caused the instrument to record a rise in temperature. He called the invisible rays 'infrared'.

We now know that the strongest infrared sources are relatively cool objects, such as red giant stars, nebulae, planets and comets, whose temperatures are between about 70 K and 3000 K. In contrast, the Sun is a fairly weak infrared emitter. With its surface temperature of about 5500 K, our nearest star emits most of its radiation at visible wavelengths. Herschel's discovery was only made possible because of the Sun's close proximity.

Little progress towards understanding the infrared universe was made until the invention of more sensitive, electronic detectors in the 1950s. Some notable exceptions were the detection of infrared emission from the Moon by Charles Piazzi SMYTH in 1856, and infrared observations of the Moon through its cycle of phases by the 4th Earl of ROSSE, who attempted to calculate its surface temperature. The first infrared observation of an object outside the solar system seems to have been made in 1878 by Thomas Edison, who observed the star ARCTURUS during a solar eclipse.

Not until 1969 was the first infrared sky survey undertaken by Gerry Neugebauer and Bob Leighton from Caltech. With the aid of lead sulphide detectors, their relatively crude 1.5 m (60 in) diameter telescope scanned 70% of the sky and detected 5612 cosmic infrared sources at 2.2 μm. More recently, detectors have been made from germanium doped with copper, mercury or gallium. Unfortunately, while these are able to probe to longer wavelengths, they require cooling to very low temperatures (2 K) in order to eliminate background interference.

Another problem to be overcome by ground-based observatories was the absorption of infrared radiation by gases such as water vapor and carbon dioxide in the Earth's atmosphere. Fortunately, in the near-infrared and mid-infrared regions, from 1 to 10 μm, there are some clear atmospheric 'windows'. From observatories on high mountain peaks, astronomers are able to use these 'windows' to investigate the infrared sky at certain wavelengths.

Most observations are obtained by means of near-infrared detectors attached to optical telescopes. For example, the 5 m (200 in) Hale telescope on Mount PALOMAR has recently been fitted with a near-infrared camera which operates at 1–2.5 μm, while the 8 m (300 in) units of the Very Large Telescope in Chile utilize a cryogenic infrared spectrometer and array camera (ISAAC) which observes in the spectral region 0.9–5 μm.

Modern instruments attached to smaller telescopes can also return data of major importance. The latest census of the near-infrared sky, known as the Two Micron All Sky Survey (2MASS) project, began in June 1997. 2MASS uses two new, highly automated 1.3 m (51 in) telescopes, one at Mount Hopkins in Arizona, and one at CERRO TOLOLO in Chile. Both telescopes are equipped with a three-color infrared camera, each channel consisting of a 256 $\times$ 256 array of detectors which is capable of observing the sky simultaneously at 1.25, 1.65 and 2.17 μm.

The development of large-format infrared detector arrays, funded by the US Department of Defense and NASA, has made the new survey possible. These mercury–cadmium–tellurium detectors, similar to those developed for the Near Infrared Camera and Multi-Object Spectrometer on the HUBBLE SPACE TELESCOPE, can now detect astronomical objects over 100 million times fainter than those seen by the original Two Micron Survey.

When completed, the 2MASS survey will contain accurate positions and fluxes for some 300 million stars and other unresolved objects, together with positions and total magnitudes for more than a million galaxies and nebulae, including galaxies in the 60° wide 'zone of avoidance', where dust within the Milky Way renders optical galaxy surveys incomplete. Rare objects such as extremely low-luminosity stars and brown dwarfs, or heavily dust-obscured AGNs and globular clusters located in the galactic plane, should also be discovered. (For further information see http://www.ipac.caltech.edu/2mass/)

Despite such advances, the best site for ground-based infrared observations remains the 4200 m (13 800 ft) high Mauna Kea in Hawaii. Located on its summit are the two largest purpose-built infrared telescopes in the world, the 3 m (120 in) NASA INFRARED TELESCOPE FACILITY and the 3.8 m (150 in) UNITED KINGDOM INFRARED TELESCOPE. Nearby are the twin 10 m (400 in) Keck telescopes and the 3.6 m (140 in) CANADA–FRANCE–HAWAII TELESCOPE, which are used for both optical and infrared observations.

However, even the Mauna Kea site is not high enough to allow far-infrared observations. In order to rise above the bulk of the water vapor and the atmosphere, astronomers have turned to placing telescopes on balloons, sounding rockets or high-flying aircraft.

In 1972 and 1974, the US Air Force Cambridge Research Laboratories (later known as the Air Force Geophysics Laboratory) carried out project HISTAR to survey the sky at various wavelengths between 4 and 27 μm. Using a liquid helium-cooled 16.5 cm (6.5 in) telescope on nine suborbital rocket flights, the project cataloged over 2000 infrared sources.

This was soon followed by the introduction of NASA's Kuiper Airborne Observatory (KAO), a modified Lockheed C-141 military aircraft equipped with a 90 cm (36 in) infrared telescope. After 20 years and more than

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

1500 flights, budget cuts brought the KAO to an end on 13 October 1995.

However, a much larger, more powerful successor is scheduled to become operational in 2002. NASA's Stratospheric Observatory for Infrared Astronomy (SOFIA) will fly on board a modified Boeing 747-SP aircraft at an operational height of 12.5 km (nearly 41 000 ft). From this altitude, SOFIA will be above 99.9% of the infrared-absorbing atmospheric water vapor that limits ground-based infrared observations.

With its European-made 2.7 m (106 in) primary mirror, SOFIA will be one of the most capable infrared observatories in the world. It will operate primarily at infrared and submillimeter wavelengths, from 0.3 to 1600 μm, though it can also be used for visible observations. Despite its size, SOFIA has been designed to meet the stringent weight requirements of an airborne telescope, and the complete system is expected to weigh only about 20 tonnes (44 000 lb).

The observatory is expected to provide unprecedented views of regions of star formation in interstellar dust clouds, circumstellar dust disks, distant comets and moons, as well as spectral information on complex molecules in space, planetary atmospheres and nearby galaxies.

SOFIA is being developed by the American Universities Space Research Association (USRA), which will also operate the telescope for NASA once it becomes operational. Under an international agreement between the United States and the German government, the German Aerospace Research Centre (DLR) is responsible for the design and construction of the SOFIA telescope. In return for supplying the telescope and part of the funding for its operation, German astronomers will receive 20% of SOFIA's observing time.

Institut de Radio Astronomie Millimétrique

The Institut de Radio Astronomie Millimétrique (IRAM) is an international scientific institute covering all aspects of radio astronomy at mm wavelengths. In this spectral range thousands of molecular emission lines allow the study of physics and chemistry in the interstellar medium, and the coldest parts of the universe can be observed through the continuum emission of dust.

The IRAM headquarters are located in Grenoble, France. The institute operates two unique observatories which are available for the astronomical community. One is a radio interferometer, consisting of currently five (soon six) 15 m diameter antennas on the Plateau de Bure in the French Alps, with imaging capabilities at an angular resolution below one arcsec. The other is a 30 m diameter telescope, located at an altitude of 2900 m on the Pico Veleta in southern Spain, with a support base in Granada.

IRAM was founded in 1979 by the German Max-Planck-Gesellschaft and the French Centre National de la Recherche Scientifique. The Spanish Instituto Geográfico Nacional, initially an associate member, became a full member in 1990. About 130 people are currently working at IRAM, most of them engineers and technicians.

The objectives of IRAM include the development and production of instrumentation for mm wave astronomy, such as extremely low-noise receivers, superconducting (SIS) detectors, and fast digital spectrometers. They also include the development of data reduction software.

In addition to supporting the user community, the IRAM astronomers perform forefront research in several fields, from the solar system to cosmological distances. Among the scientific highlights from the IRAM observatories are the detection of molecular gas in high-redshift objects, the mapping of CO and dust emission in nearby galaxies, the investigation of circumbinary disks and proto-planetary disks around pre-main sequence stars, and also observations of molecular line and continuum emission of comets and other solar-system objects.

Institut National des Sciences de l'Univers

The Institut National des Sciences de l'Univers (INSU) was created in 1985, under the joint authority of the French Ministry of Higher Education and the CNRS. INSU is responsible for the major facilities and programs in the fields of astronomy and Earth sciences, including the Universe Sciences Observatories.

INSU operates major research facilities, both for collecting data (by satellite, oceanographic ship, atmospheric research aircraft or multisite field campaigns), and for the computer processing and interpretation of the collected data with data bases, models and numerical simulations.

It also has administrative and technical divisions designed to help implement policies. The mission of the technical division is to design projects for the necessary equipment and instruments and to operate the French facilities.

Sciences of the Universe are also represented as a department within the CNRS, and both the CNRS department and INSU are headed by the same director. The department has responsibility for CNRS-associated laboratories and personnel and, with the help of the National Committee, for the analysis of overall scientific trends.

Institute of Space and Astronautical Science

The Institute of Space and Astronautical Science (ISAS) is situated in Sagamihara, Japan. ISAS is a central institute for space science research belonging to the Ministry of Education, and functions as an inter-university research organization. It was established in April 1981 by reorganizing the Institute of Space and Aeronautical Science, University of Tokyo. ISAS consists of around 300 staff, which include professors, associate professors, research associates, technicians and administrative staff. The major facilities are: Kagoshima Space Center (rocket launch), Noshiro Testing Center (static firing test of rocket motors), Sanriku Balloon Center (scientific balloon launch) and Usuda Deep Space Center (deep space communication). ISAS is one of the leading agencies in the world in some fields of space science, e.g. x-ray astronomy, space plasma physics, solar physics and radio astronomy. The latest version of its satellite launch vehicle is the M-V rocket, which launches almost one satellite per year into space.

Instituto Argentino de Radioastronomía

The Instituto Argentino de Radioastronomía (IAR) is an astrophysics research center and radio astronomical observatory located 40 km from Buenos Aires, Argentina. It was built during 1962–65 and officially inaugurated on 26 March 1966.

The primary instruments of the institute are two 30 m single dish radio telescopes which provide a coverage of the southern sky from declinations of -90° to -10°. The maximum tracking time on a given source is about four hours. The telescopes are used with receivers that operate at 1420 MHz, 1670 MHz and 3.3 GHz. The neutral hydrogen line (21 cm) can be observed with a helium-cooled HEMT receiver and a 1008-channel autocorrelator at the backend. The HPBW of the telescopes is $\sim$15 and $\sim$30 arcmins at 3.3 GHz and 1.4 GHz, respectively.

IAR's observing facilities have been used to survey the extended H I line emission in the southern sky and, in recent years, to study the variability of extragalactic radio sources on short time-scales. Many new supernova remnants and radio counterparts of gamma-ray sources have been also discovered with these telescopes.

In addition to the astronomical instruments, the IAR has a laboratory of electronics, a department of mechanics, and a well-stocked library. There is an open policy for granting telescope time on the basis of refereed proposals.

Instituto de Astrofisica de Canarias

The Instituto de Astrofisica de Canarias (IAC) and its Observatories—the OBSERVATORIO DEL TEIDE on Tenerife and the OBSERVATORIO DEL ROQUE DE LOS MUCHACHOS on La Palma—are a Spanish research center open, from 1979, to the international scientific community through its Agreements on Cooperation in Astrophysics. The IAC Observatories in fact form the European Northern Observatory (ENO), in which instruments have been installed from over thirty scientific institutions belonging to Belgium, Denmark, Finland, France, Germany, Holland, Ireland, Italy, Norway, Spain, Sweden and the United Kingdom. The Observatories were inaugurated in 1985 by the Spanish Royal Family in the presence of six other European heads of state.

Although it was created in 1982 as a Public Consortium in partnership with the Spanish State, the Autonomous Canarian Government, the University of La Laguna and the Higher Council of Scientific Research (CSIC), the IAC inherited the Observatorio del Teide, which was created in 1959.

The IAC's activities include astrophysical research, the development of ground-based and space-borne instrumentation, the training of researchers, university education and popularization. Its central headquarters are a scientific-technical institute, whose resources include a library, a computer center, workshops and laboratories. Over 300 people work at the IAC, including scientific, technical and administrative personnel.

The IAC's research program consists of projects covering the universe and cosmology, stars, the Sun, interstellar matter, planetary systems, atmospheric optics, high spatial resolution, the design and construction of telescopes, and space-borne optical and infrared instrumentation. Among these projects should be highlighted the 10 m large telescope (the Gran Telescopio de Canarias, GTC), which will become operative at the Observatorio del Roque de los Muchachos at the end of 2003.

Instrumentation: Adaptive Optics

Turbulence in the Earth's atmosphere produces inhomogeneities in the refractive index of the air, which affect the image quality of ground-based telescopes (see SEEING). ADAPTIVE OPTICS (AO) is a means for the real-time compensation of image degradation. It consists of using an active optical element such as a deformable mirror to correct the instantaneous wave-front distortions. These are measured by a device called a wave-front sensor which delivers the signals necessary to drive the correcting element.

First proposed in 1953 by the astronomer Horace Babcock, the technique was developed only in the 1970s, mainly for defense applications (optical surveillance). The first operational astronomical AO system was built in France and successfully tested in October 1989 in OBSERVATOIRE D'HAUTE PROVENCE. It was later installed on the 3.6 m telescope at the EUROPEAN SOUTHERN OBSERVATORY. Since 1994, a growing number of observatories have been equipped with AO systems, mostly in the United States of America.

Figure 1 shows a schematic diagram of a typical astronomical AO system. It consists of three main components, a deformable mirror, a wave-front sensor and control electronics. They operate in a closed feedback loop. The deformable mirror first compensates the distortions of the incoming wave-front. Then a beam splitter diverts part of the light toward the wave-front sensor to estimate the residual wave-front distortions. The control system uses the wave-front sensor information to update the deformable mirror figure. As the incoming wave-front evolves, these operations are repeated indefinitely at a rate of the order of a thousand times per second.

Wave-front sensors require the use of a so-called 'guide' source. They work best on a point source. Fortunately, nature provides astronomers with many point sources, in the form of stars. However, they are quite faint. With current systems, observations are limited to the vicinity of bright stars, that is a small fraction of the sky. Wave-front sensing is also possible on extended sources if they are sufficiently bright and compact. Examples are solar system objects such as small planets, satellites or asteroids, but also a few galaxy cores or even small nebulosities. Solar astronomers are now able to do wave-front sensing on the solar surface. To improve the ability to sense the wave-front, a number of researchers are also producing artificial light sources by illuminating the atmosphere with a powerful laser beacon. Unfortunately, the laser beacon itself is affected by atmospheric turbulence, and stellar sources are still needed to complement the information. Today, laser systems are costly and have not yet fully come up to expectations.

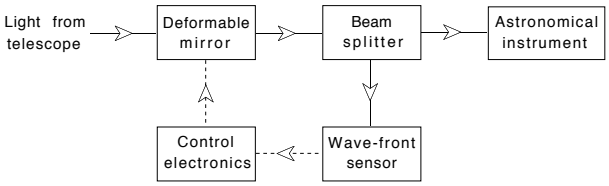

Figure 1. Schematic diagram of an AO system.

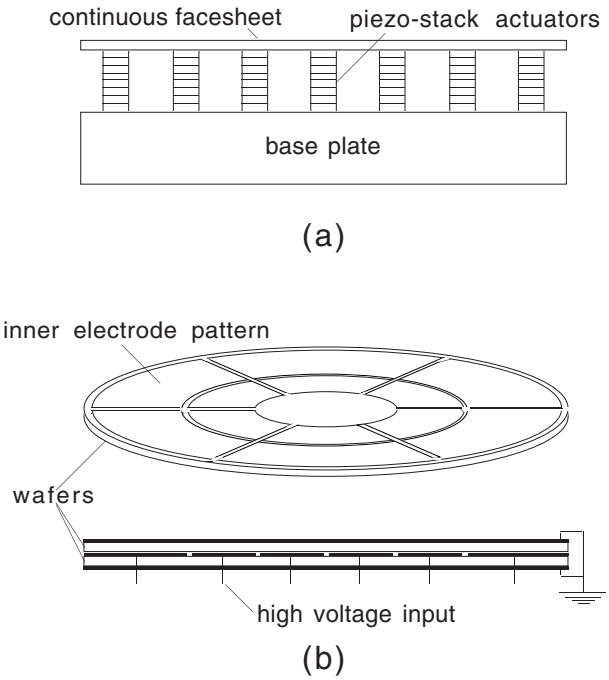

Figure 2. Deformable mirrors: (*a*) conventional, (*b*) bimorph.

Current technology

Currently, there are two competing technologies referred to as 'conventional' versus 'curvature' AO systems. Conventional systems are based on components developed in the industry: Shack–Hartmann wavefront sensors with charge coupled devices (CCD) detectors, and continuous facesheet mirrors with piezo-stack actuators. Curvature systems are based on a new approach pioneered at the Institute for Astronomy in the University of Hawaii (UH), and first used at the CANADA–FRANCE–HAWAII TELESCOPE (CFHT) on Mauna Kea. A novel wave-front 'curvature' sensor is used together with an array of discrete photon counting avalanche photodiodes (APDs) for light detection. Also a new deformable mirror technology is used based on piezo bimorph wafers.

Figure 2 shows the two main types of deformable mirrors used in astronomy. Conventional mirrors consist of a thin plate of glass or silicon supported by an array of stacked piezoelectric or electrostrictive actuators. Actuators push or pull on the plate producing local bumps or dips (figure 2(*a*)). Bimorph mirrors consist of a pair of piezoelectric wafers glued together with electrodes in between and outside. The wafers are polarized perpendicular to the surface. When voltages are applied to the electrodes, electric fields are produced inside the

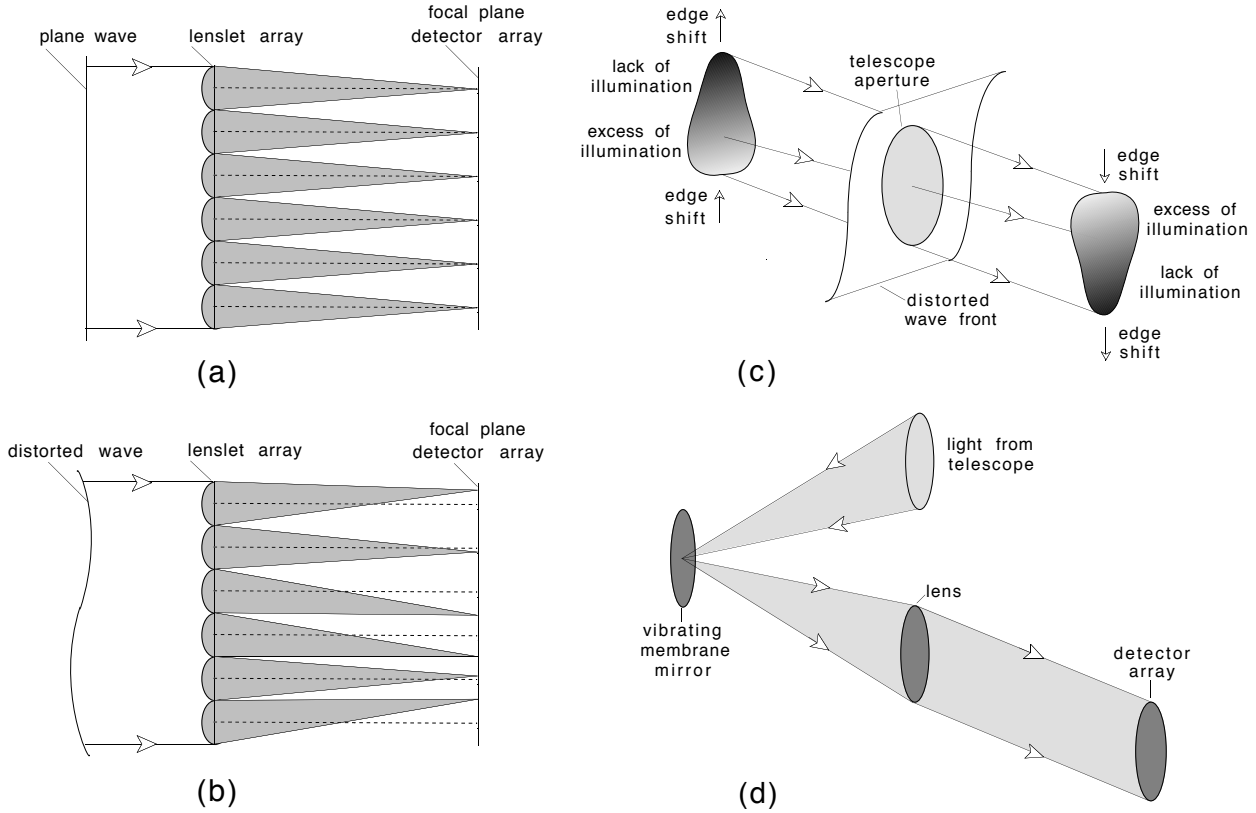

Figure 3. Wave-front sensors: (a, b) Shack–Hartmann sensor, (c, d) curvature sensor.

wafers so that one wafer contracts whereas the other one expands, locally bending the mirror (figure 2(b)). In all cases, digital to analog converters and high-voltage amplifiers are used to produce the voltages necessary to deform the mirror (typically a few hundred volts).

Figure 3 shows the two main types of wave-front sensors. A Shack–Hartmann sensor consists of an array of small lenses set in a plane conjugate to the telescope aperture. Each lenslet forms an image of the guide source on a CCD detector array (figure 3(a)). By comparison with a reference plane wave, a distorted wave-front produces shifts in the location of each of these images (figure 3(b)). A measure of the shift gives an estimate of the local wave-front slope. Mathematically, the wave-front surface can be reconstructed by integrating these wave-front slopes along two orthogonal directions. It can be shown that a least-square solution is obtained by computing the wave-front Laplacian (total curvature) from the slopes. The Laplacian is then integrated by solving a Poisson equation with radial edge slopes as boundary conditions.

A curvature sensor directly gives estimates of the wave-front Laplacian and radial edge slopes. This is done by comparing the illuminations in two symmetrically defocused images of the telescope aperture (figure 3(c)). Differences in the illumination give a measure of the local convergence or divergence of the beam, that is of the wave-front total curvature (Laplacian). Differences in the position of the aperture edges gives a measure of the local edge ray inclination, that is of the wave-front edge slope. In practice a vibrating membrane mirror is used to defocus back and forth an image of the telescope aperture (figure 3(d)). Any deviation of the wave-front surface from a plane wave produces a modulation of the light intensity at the frequency of the membrane drum oscillations (kHz rate). A phase-locked demodulation produces the sensor signals.

Real-time computers are used to control the feedback loop. Conventional systems use a wave-front computer to calculate the centroids of the Shack–Hartmann subaperture images. The coordinates of the centroids are compared with reference coordinates, and the differences form the sensor signals. Curvature systems use a two-channel counter to count photons during each half cycle of the membrane vibration. The differences in photon counts form the sensor signals. No reference is needed. In all cases, a control computer is used to convert the sensor signals into the voltages one must apply to the deformable mirror. This is done by multiplying the sensor signals with a control matrix. The control matrix is often determined experimentally with a calibration light source. The deformable mirror actuators are excited sequentially and the corresponding sensor responses are recorded. The

resulting interaction matrix is then inverted through a singular value decomposition to produce a control matrix. The eigenmodes of the control matrix are called the system modes. The eigenvalues are the loop gains of each mode. These gains can be individually modified to minimize the effect of sensor noise. The procedure is called modal control.

Performance and limitations

Figure 4 shows an example of three different profiles of the intensity distribution in a stellar image, also called the point spread function (PSF). The left profile is for an uncompensated image, and is often referred to as the seeing disk profile. The center profile is for a partially compensated image obtained with an AO system turned on. The right profile, often referred to as the AIRY DISK profile, is the theoretically ideal profile of the diffraction-limited image one would obtain with perfect optics and no atmosphere. Astronomers are used to measuring image quality in terms of the angular full width at half maximum (FWHM) of a stellar image. Expressed in radians, the FWHM of an Airy disk profile is very close to λ/D, where λ is the wavelength of light and D is the telescope diameter. That of a seeing disk profile is very close to λ/r_0, where r_0 is a seeing parameter first introduced by David Fried (1966) and now called the Fried parameter. Figure 4 shows that the FWHM of a partially compensated PSF is much closer to that of the Airy disk than to that of the seeing disk. This is because a compensated PSF consists of a narrow (almost diffraction-limited) core, on top of broad halo, barely narrower than the seeing disk. The halo is due to the light diffracted by the small-scale wave-front distortions which have not been compensated by the AO system.

A consequence is that the FWHM is a poor quality criterion for an AO-compensated image. A more widely used criterion is the Strehl ratio, which is the ratio I_c/I_d of the maximum intensity in the compensated PSF to that in the diffraction-limited PSF obtained with the same telescope (see figure 4). Visually, an image appears fairly sharp if its Strehl ratio is greater than 0.3. It appears blurry if it is less than 0.3. Following Fried, AO specialists also use another criterion called the normalized Strehl ratio or normalized resolution, which is the Strehl ratio of the compensated PSF divided by that of the pure seeing disk. If one neglects diffraction in the uncompensated PSF, then the normalized resolution is simply I_c/I_u (see figure 4). This criterion has the advantage of being telescope independent.

Figure 5(*a*) shows theoretical curves for the normalized resolution as a function of D/r_0. These are for zonal compensation over N subapertures assuming no wave-front sensing error. The curve labeled (0) is for uncompensated images. Atmospheric turbulence is supposed to follow Kolmogorov statistics. The performance of real AO systems follows very similar curves except that the actual number N_a of actuators is typically two to five times larger. The ratio N/N_a is a measure of the system compensation

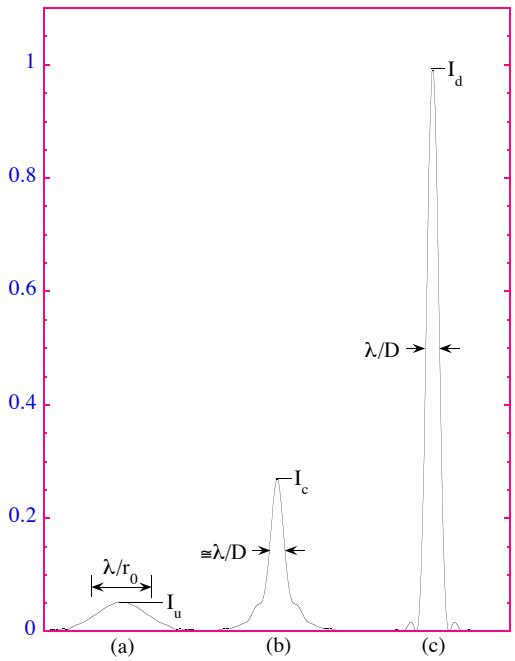

Figure 4. Intensity profiles for three different point source images: (*a*) uncompensated, (*b*) compensated, (*c*) diffraction-limited. For the clarity of the figure we have plotted only results for image motion compensation under very good seeing conditions ($D/r_0 = 4$).

efficiency. It is limited by errors due to finite wave-front sampling both in space and in time. It is interesting to note that the Strehl ratio improvement brought by adaptive optics goes to a maximum for $D/r_0 = 2.3\sqrt{N}$. At this point the gain is by a factor of $1.6N$, and the Strehl ratio of the compensated image is about 0.3.

When a faint source is used to sense the wave-front, there is an additional loss of Strehl ratio (or compensation efficiency) due to measurement noise, including photon shot noise, read-out noise and sky background noise. Curvature AO systems with photon counting APDs have constantly outperformed other systems on faint guide sources. Figure 5(*b*) shows the actual performance of three curvature systems which have been used on the CFHT: the 13-actuator UH prototype, the 19-actuator CFHT user instrument (Pueo), and the 36-actuator UH system called Hokupa'a. The broken curve indicates the projected performance for an 85-actuator curvature AO system. It is interesting to note that the limiting magnitude is independent of the number of actuators as one expects from pure photon shot noise.

Another loss of Strehl ratio occurs when the guide source is away from the observed object. This is because the two wave-front distortions differ, a property called anisoplanatism. On a 3.6 m telescope such as the CFHT, the observed loss of Strehl ratio is typically 10% over a distance of 10 arcseconds. This number depends heavily on seeing conditions.

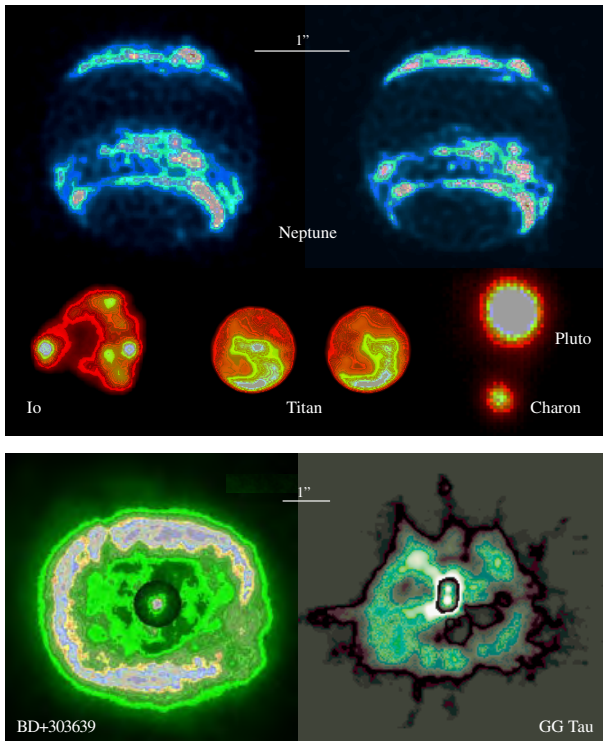

Figure 6. Examples of astronomical images recorded with adaptive optics. **This figure is reproduced as Color Plate 32.**

Examples of astronomical images

Figure 6 shows examples of infrared astronomical images obtained with adaptive optics. The upper part shows solar system objects all at the same scale. From top to bottom and left to right are two images of NEPTUNE showing rotating cloud bands, an image of IO showing glowing lava flows during an eclipse in the shadow of JUPITER, two images of TITAN showing a rotating surface feature, and an image of PLUTO AND CHARON. The bottom part shows circumstellar structures at a scale twice smaller: a PLANETARY NEBULA around an evolved star BD+303639 (bottom left) and a DUSTY CIRCUMSTELLAR DISK around a young star GG Tau (bottom right). In both cases the central source is displayed with an attenuated intensity scale. The images of Io, Pluto–Charon and GG Tau were obtained at the CFHT with the UH 13-actuator prototype AO system. The other images were obtained with the UH 36-actuator Hokupa'a system either at the CFHT (Neptune and Titan) or on the 8-m GEMINI telescope (BD+303639). In all cases the object itself was used as a guide source except for Io where nearby EUROPA was used.

Interacting Galaxies

Galaxies that interact with each other during close encounters or collisions. In a close encounter between two galaxies, both are distorted by gravitational tidal forces. Typically, matter will be pulled into bulges on both sides of each galaxy and, depending on the angular momentum (a quantity that depends on the distribution of mass and rotational velocity within each galaxy) of each galaxy and on the minimum separation and relative velocity of the two galaxies, stars and gas clouds may be flung out into long, looping 'tails' and/or material may flow into bridges that link the galaxies together. The pair of galaxies, NGC 4038 and 4039, which is known as the 'Antennae' because of the huge pair of antenna-like arms that curve away from the main bodies of the two colliding galaxies, appears to be a classic example of this process in action. Close encounters may also be responsible for initiating spiral structure in some galaxies.

When two galaxies collide, their individual member stars do not themselves collide (the average separation between stars is so great that the chance of any direct stellar collisions taking place is microscopic), but their constituent gas clouds do. Through mutual interactions, some stars will gain energy and be ejected from the member galaxies; others will lose energy and fall towards the center of mass of the two galaxies. A possible outcome of this process is that the two galaxies will merge into one. In some situations, collisions between their constituent gas clouds may strip one or both galaxies of their gas. This gas, heated by the violence of the collision, is then added to the tenuous distribution of high-temperature intergalactic gas that is known to be present in many clusters of galaxies. In other cases, gas clouds that have been compressed through collisions or tidal interactions collapse on themselves and trigger dramatic bursts of star formation. This process may account for the existence of starburst galaxies, highly luminous galaxies that shine with the light of large numbers of newborn stars. Where a compact galaxy passes through a larger spiral galaxy, it can initiate star formation in a ring within the larger galaxy's disk. The 'Cartwheel' Galaxy, for example, appears to be the result of an event of this kind.

Because most galaxies are members of groups and clusters within which the average separation of galaxies is ten to a hundred times the average diameter of a galaxy, close encounters, collisions and mergers are common events that play a major role in the evolution of galaxies and clusters. If small galaxies make close encounters with, or collide with, larger, more massive, ones, the smaller galaxies may be completely disrupted and absorbed by the larger ones. This process of 'galactic cannibalism' causes large galaxies to grow at the expense of smaller ones and is believed to be responsible for the existence of giant elliptical galaxies in the centers of richly populated clusters of galaxies.

Interference

The pattern of light and dark obtained when two beams of light combine or interfere with each other. If two waves of the same wavelength and amplitude have the same phase (i.e. their crests and troughs are in step), then the crests will enhance each other to produce a bright fringe light. If they are exactly out of phase, then the crests of one wave and the troughs of the other will cancel each other out, so producing a dark fringe. These patterns are also referred to as interference fringes. Such patterns may be formed with any type of electromagnetic radiation (or with other types of waves, water waves, for example), and the interpretation of these interference patterns forms the basis of the technique of interferometry.

An interferometer makes use of the phenomenon of the interference of electromagnetic wavefronts arriving at two separate detectors to attain more precise position measurements or better resolving power than could be achieved with a single telescope or detector.

For example, a typical radio interferometer consists of two telescopes, separated by a known distance. Both telescopes are used to study the same source. Because of the separation of the two receivers, there is a small delay between the arrival of a given radio wave at the first and second radio telescope (i.e. the wavefronts arriving at any instant at the two receivers will be out of phase, in general, and will interfere with each other if they are combined). The combined signal is analyzed and, for example, as the source moves across the sky, the analysis of the changing interference pattern will yield a precise position of the source.

For a given wavelength of radiation, the greater the separation of the telescopes the higher the resolving power achieved. The most precise position measurements in radioastronomy have been made by long-baseline interferometry, combining signals from two radio telescopes separated by thousands of kilometers. The longest baseline so far achieved is between California and Australia, some 10 600 km, by means of which a resolving power of 0.001 seconds of arc has been achieved at a wavelength of 13 cm.

Interferometer

A device that utilizes interference effects between two or more light or other types of waves in order to attain higher angular resolutions than can be attained by a single telescope or other device.

The underlying principle of interference is as follows. If two light waves of the same wavelength are combined in phase (i.e. the wavecrests of one wave are in step with the wavecrests of the other) they add together to produce a wave of greater amplitude (this process is called constructive interference). Conversely, if two waves are 180° out of phase (the crests of one coinciding with the 'troughs' of the other), they cancel out, so producing a wave of zero amplitude (destructive interference). If two beams of light, originating from a single source, follow paths of different lengths and are then recombined, they will interfere with each other, producing bright fringes where they arrive in phase and dark fringes where they arrive out of phase. Likewise, beams of light originating from different parts of the same source, or from separated sources, will interfere when combined. The pattern of fringes, or interference pattern, that is produced in this way can be analyzed to yield information about the different path lengths that the beams have followed and hence to provide information about the angular size of a source, the angular separation between different parts of the same source, the angular separation between two separate point sources or the location of the source on the sky.

The interferometer was invented by Albert A Michelson (1852–1931) in 1881 in order to measure differences in path length for light beams, and has since had a wide variety of applications. A subsequent version, the Michelson stellar interferometer, consisted of two separate apertures, or slits, placed in front of a large telescope. In principle, when light from a single star, or a double star, passed through the two slits and recombined at the focus of the telescope, analysis of the resulting interference pattern allowed the angular diameter of a large star or the angular separation between the components of the binary to be measured. The resolving power of an interferometer of this kind depends on the separation between the apertures or slits; the larger the separation the better the resolution ($R = \lambda/2D$, where R = angular resolution in radians, λ = wavelength and D = the separation of the apertures). Later versions extended the separation between the apertures by means of mirrors placed on a beam located across, and extending beyond, the aperture of the telescope itself.

The radio interferometer combines the signals received by two (or more) separate radio dishes. As the source (or sources) is carried across the sky by the Earth's rotation, the advancing wavecrests have different distances to travel before reaching each of the two dishes and move in and out of phase with each other, so producing an interference pattern, which can then be analyzed. The greater the separation of the dishes (the baseline), the better the resolution. High resolution is obtained only along a direction parallel to the baseline. However, if use is made of the Earth's rotation (to change the orientation of the baseline relative to the sky), and the separation between dishes can be varied, then a series of observations can yield an image equivalent to that which would be produced by a single dish equal in aperture to the maximum separation between dishes. This technique is called aperture synthesis. Because light waves are many orders of magnitude (typically a million times) shorter than radio waves, the tolerances necessary to use separated optical telescopes as interferometers or aperture synthesis systems are orders of magnitude finer than those that radioastronomers have to achieve. Consequently, although optical fringes produced by two separate telescopes were first observed by French astronomer Antoine Labeyrie in 1975, it is only in very recent years that optical astronomers have begun to be able to use separated telescopes to good effect as interferometers and aperture synthesis systems.

The COAST (Cambridge Optical Aperture Synthesis Telescope) system achieved optical resolutions of around 0.01 arcsec in 1995. The twin 10 m Keck telescopes (on Mauna Kea, Hawaii) and the four 8 m mirrors of the Very Large Telescope (on Mount Paranal, Chile) are each expected to be able to achieve milliarc second resolutions when they become operational in interferometer and aperture synthesis modes.

Interferometry: Ground

Astrometry is the measurement of angular positions of stars. Historically, this was done by measuring the position of a stellar image in the focal plane of a telescope using for example a CCD, a photographic plate or the observer's eye. When changes in position over a small field of view are required—for PARALLAXES or astrometric orbits of BINARY STARS—the star's position is measured relative to other stars within the telescope's field of view. This is called narrow-angle astrometry. Global positions needed for reference frame problems require wide-angle astrometry. Here the telescope's orientation is known relative to the Earth and is called a transit circle.

The astrometric precision is limited by the size of the star's image in the telescope's focal plane, which in turn is limited by diffraction of light at the edges of the telescope's aperture. The larger the aperture, the smaller the image and the more precise the astrometric measurement. The angular resolution can be increased by combining light from multiple telescopes. Done properly, this is called optical interferometry and the resolution now depends on the baseline, the distance between the two telescopes instead of on the diameter of the telescope apertures. With this technique, the resolution, hence the precision of the measurement, can be improved simply by increasing the baseline. Baselines much longer than the diameter of the largest telescope are possible. (See also ASTROMETRY: TELESCOPES AND TECHNIQUES.)

The astrometric accuracy, however, is limited by systematic effects and not by the precision of the measurements. The atmosphere produces the largest systematics: anomalous refraction, image blurring and motion. These effects favor the use of an INTERFEROMETER.

Anomalous refraction

The Earth's atmosphere bends light, making stars appear higher in the sky than they actually are. This is because air has a larger index of refraction than empty space. As light enters a region of higher index of refraction it is bent toward the direction of the gradient. Since the air's index of refraction depends on both its temperature and pressure and therefore, on the local meteorological conditions, the stellar refraction will, in general, depart from that caused by the mean atmosphere. This departure is anomalous refraction and limits the accuracy of astrometric measurements. Although monitoring the atmosphere with the hope of correcting the data for anomalous refraction could be done, the required accuracy of the measurements is greater than what can be obtained. For example, at a zenith angle of 45°, an error in the mean temperature along the line-of-sight of only 0.5° will result in an astrometric error of 0.1 arcseconds.

For wide-angle astrometry, an interferometric measurement should be of higher accuracy because it is inherently differential; it compares the difference between the optical paths from the star to where the light is combined from the two telescopes. To the extent that the atmosphere is the same over both telescopes, its effect cancels. This cancellation is a strong argument for using an interferometer for ground-based astrometric measurements.

Image blur and motion

The weather patterns that give rise to anomalous refraction can be relatively constant over periods of hours. There are, however, random fluctuations in temperature and pressure which occur on much faster time scales. These are the same fluctuations responsible for shimmer seen when looking toward the horizon on a hot day; and for the scintillation (twinkling) of stars at night. Although scintillation does not directly affect the astrometry, it is accompanied by a distortion of the wavefront that results in image blur in a large telescope and image motion in a small telescope. These effects directly impact both the accuracy and precision of the astrometric measurement.

As with most optical media, the index of refraction of air increases with decreasing wavelength. As a result, atmospheric refraction is larger at shorter wavelengths. In principal, this shift of the stellar image with wavelength can be measured and used to estimate the total atmospheric refraction. In practice, the wavelength dependence is too small to be practical for telescopic observations. This situation is different for the interferometer which maintains its high precision looking through the atmosphere; for an interferometer, this technique is feasible and has been demonstrated.

Background

The workings of an OPTICAL INTERFEROMETER can be described in two ways. In the previous section, we described an optical interferometer as giving a higher resolution image than that obtained with a single telescope. Although this is true, an astrometric interferometer usually does not form an image; it is better to think of its operation in terms of interference fringes.

Interference fringes

The schematic of a simple optical interferometer is shown in figure 1. Two telescopes, pointing at the same star, intercept sections of a single wavefront of light. Those sections of wavefront are combined at the beam splitter, BS. The detectors D_1 and D_2 each see half the light from each section of wavefront. The interferometer is aligned when the wavefronts entering the detectors are parallel to each other and the path length from the star to the beam splitter is the same regardless of which telescope intercepted the light. The path lengths are equalized with delay lines which consist of mirrors on a cart that can be moved to change the delay internal to the interferometer.

A change of the internal delay shifts the relative phase of the two waves reaching a detector. When the waves are exactly in phase, they superimpose, reinforcing each other. They result in a larger amplitude and more light. This is called constructive interference. When the wave are 180°, or half a wavelength, out of phase, they cancel each other with one at a maximum while the other is at a minimum.

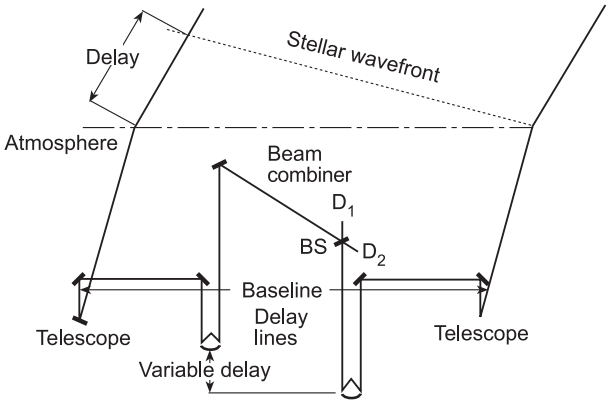

Figure 1. Layout of a simple Michelson interferometer.

This case results in no light at the detector. This is destructive interference. In an astrometric interferometer, the fringe is detected as a variation of intensity as a function of delay in the combined beams.

To look at this from another perspective, consider a perfect beam splitter for which the reflected beam is retarded by a quarter wave (90° of phase) relative to the transmitted beam. When the internal delay exactly matches the external delay, the light from one telescope is a quarter wave retarded relative to the light from the other telescope when it reaches detector D_1 but is a quarter wave advanced when it reaches detector D_2. In both cases, there is quarter wave phase shift between the two waves so the two detectors see equal light. This is exactly what is expected since the system is completely symmetric. When the internal delay changes, the phase difference increases at one detector and decreases at the other. The output of the detectors varies sinusoidally with phase but since they are 180° out of phase, the total amount of light is constant.

The fringe packet and temporal coherence

We have seen how interference fringes are formed. As the delay changes, the outputs of the beam combiner oscillate. These intensity oscillations have a period of one wavelength. Now, consider what happens when the interferometer passes light over a range of wavelengths. When the path lengths are equal, all wavelengths interfere constructively. But since the blue fringes are shorter than the red fringes, as the delay difference increases, successive intensity maxima are broadened by the blue light reaching maximum earlier than the red light. This smearing of the colors across the peak results in a lower maximum. The same process occurs at the minimum; the blue minimum occurs before the red and the minimum at one wavelength is partially filled in by the other wavelengths. The result is reduced fringe contrast or visibility[1]. The result is each successive fringe has lower visibility. The central fringe is the highest visibility fringe and is also called the white light fringe because it is the only fringe that occurs nearly simultaneously for all wavelengths. For a bandpass of $\Delta\lambda$, centered at wavelength, λ, the visibility drops off as

$$V = V_0 \frac{\sin(\pi d \Delta\lambda/\lambda^2)}{\pi d \Delta\lambda/\lambda^2} \tag{1}$$

where V_0 is the visibility of the white light fringe, and d is the delay offset from that fringe. Thus the fringes are not visible at all delays; they are confined to a region of delays of width $\lambda^2/\Delta\lambda$ and form a fringe packet.

The path length mismatch is referred to as the delay because it can be thought of as a mismatch in the time of arrival of the wavefronts between the arms of the interferometer. For the same reason, the width of the fringe packet is referred to as the temporal coherence because it is related to the maximum timing error that can be allowed for interference to occur.

Astrometry

Because the white light fringe occurs when the internal delay equals the external (or geometric) delay, the delay can be written as

$$d_{\rm int} + C = \boldsymbol{B} \cdot \boldsymbol{s} \tag{2}$$

where $\boldsymbol{B}$ is the baseline, the vector distance between the two telescopes, $\boldsymbol{s}$ is the unit vector pointing toward the star and C is the delay constant, a zero point offset in the internal delay measurement. This equation contains four parameters that describe the instrument, the three components of the baseline and the delay constant. It also contains two unknowns for each star, the right ascension and declination. Including these parameters explicitly in equation (2) gives

$$\begin{aligned} d_{\rm int} = {} & B_{\rm x}\cos(\delta)\cos(t-\alpha) \\ & - B_{\rm y}\cos(\delta)\sin(t-\alpha) \\ & + B_{\rm z}\sin(\delta) - C \end{aligned} \tag{3}$$

where t is the local sidereal time. A right-handed coordinate system has been used with z-axis parallel to the Earth's rotation axis, y-axis pointing toward the east point on the horizon, and x-axis pointing toward the point where the celestial equator crosses the meridian.

An observation with an astrometric interferometer consists of pointing the telescopes at the same star and moving the delay lines until the white light fringe is located. The time and internal delay of the white light fringe are recorded. Figure 2 shows what a typical data set looks like for a north–south baseline. It can be seen from equation (4) and figure 2, that the delay for a star is a sinusoidal variation with a 24 h period. For two stars, the difference in the phase of this oscillation is equal to the difference in the stars' right ascensions. Moving from the equator to the pole, the amplitude of the oscillation

[1] To be precise, the fringe contrast should be called the visibility amplitude, since properly defined, the visibility is a complex number. The visibility phase depends on source structure but since it is usually zero for astrometric sources, we ignore it here.

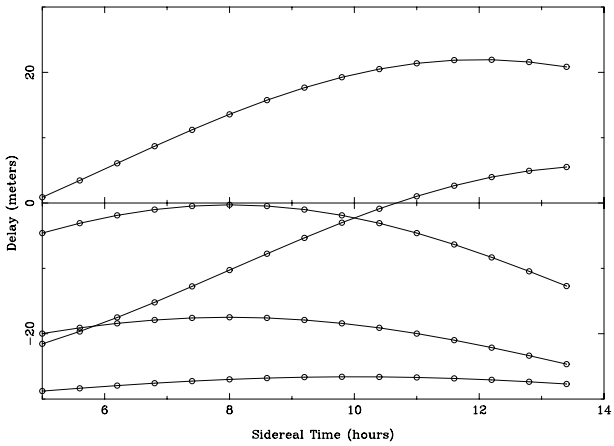

Figure 2. Delay as a function of time for a north–south baseline. Data for the same star are connected by a solid curve. Stars at higher declination show a smaller amplitude variation and the mean delay is more negative. For two stars, the difference in time between the maxima is the difference in the star's right ascensions.

decreases and its offset from zero delay increases. With enough data, the four instrumental parameters, all the declinations, and the relative right ascensions can be determined.

Although this method will work, it requires nearly horizon to horizon coverage in order to determine the amplitude, phase, and offset of the delay variations, each with errors comparable to a single measurement. Thus it is difficult to exploit partial nights of data and the observations are susceptible to slow instrumental drifts. A more robust interferometer has at least three independent baselines (four telescopes). With three baselines, three delays are measured simultaneously and the number of data increases faster than the number of unknowns as stars are added to the list of observations. In this way, the baselines and relative angles between the stars can be determined with a short set of observations. Multiple observations of the stars through the night are needed only to tie the coordinate system to the Earth's rotation axis. This type of instrument is less susceptible to subtle instrumental effects corrupting the results since the instrumental parameters can be determined from data spanning a shorter time.

Practical considerations

To achieve milliarcsecond accuracy with 100 meter class baselines, the delay must be determined with an accuracy of better than 1 μm. This implies that the internal delay, or at least changes in the internal delay needs to be measured with similar accuracy. This is while those delays are changing by several tens of meters as the observations are switched between different parts of the sky. Unmonitored changes produce noise on the astrometric data. The most important parts of the interferometer to monitor are the delay lines and the telescopes. The delay lines allow large, rapid variations of the internal delay without tilting the beam or introducing path length vibrations. A laser metrology beam, injected into the system parallel to but displaced from the stellar beam, is used for monitoring the position of the delay line cart; hence, the change in the internal delay.

At high frequencies, the signal from the laser metrology system is used for controling vibrations. At lower frequencies, it becomes the primary astrometric data.

The only moving parts in the interferometer are the delay lines and the telescopes. Since the delay lines are monitored, most of the astrometric noise is due to the telescopes; either due to bearing errors or to an offset between its mechanical and optical pivots. Bearing errors can be kept down to a few tenths of a micrometer. The pivot offsets can be controled during manufacture. Instead of zeroing the pivot-point offsets, it is more important to make the telescopes identical so that the delays introduced are the same for the telescopes at both ends of the baseline and can cancel. Alternatively, these motions can be monitored with a three-dimensional metrology system tying the position of the telescope to local bedrock.

Most of the optical paths through the system should be in vacuum. This is certainly true for the delay lines because the paths from the telescopes to the star all contain the same amount of air. Since the external delay is the difference between these path lengths, the air cancels out and the external delay can be thought of as occurring in vacuum above the Earth's atmosphere. Therefore the change in internal delay must also occur in vacuum in order to keep the air paths matched in all arms of the interferometer. If this is not done, the dispersion due to propagation through air will severely limit the observing bandpass. The rest of the path lengths do not have to be in vacuum as long as the amount of air is matched between the arms. However, the less air in the path the better since small temperature gradients will refract the light and air turbulence will degrade the stellar wavefronts, as previously described.

Finally, the mirrors in the feed optics between the telescope and the beam combination laboratory can move, introducing delay errors. Because these mirrors are exposed to the elements and can experience large temperature variations, they can be unstable and produce delay variations that may limit the performance of the system. These variations can be minimized either by monitoring the path length variations with a metrology system, or by controling and monitoring the environment so that the variations are kept to a tolerable level.

Atmospheric effects

For wide-angle astrometry, traditional measurements with a transit circle are limited in accuracy by our inability to correct the data for anomalous refraction. An interferometer measures the difference in optical path between its arms. To the extent that the telescopes sample the same atmosphere, refraction affects all the light paths

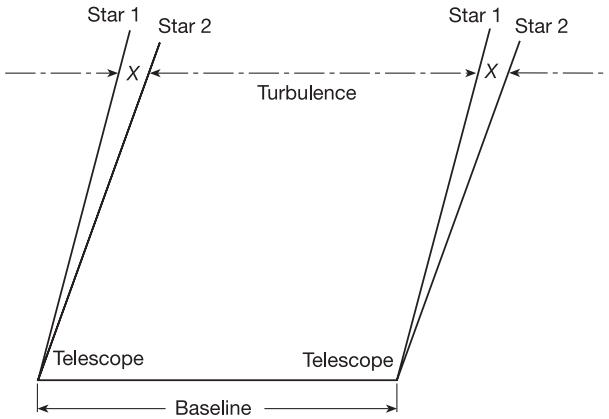

Figure 3. Diagram of the observation of two stars separated by a small angle.

the same and atmospheric refraction has no effect on the interferometer data. The major systematic error in transit circle measurements, anomalous refraction, is missing from the interferometer data.

For an interferometer, the largest systematic effect is due to the zenith angle of the star being different at the two ends of the baseline. Since the air path varies as the secant of the zenith angle, this introduces a delay error that is zero for an observation at the zenith but grows toward the horizon in the direction of the baseline. The delay error is proportional to the length of the baseline. For a 100 meter baseline, the difference between the optical and geometric paths is 2 meters at a 45° zenith angle, but the delay error is never more than 30 μm corresponding to an astrometric error of 60 milliarcseconds. By contrast, the angles measured with a transit circle are directly affected by atmospheric refraction. Thus the correction has to be calculated and applied with 1000 times the accuracy in order to achieve the same performance as the interferometer.

The atmosphere also adds random noise to the systematics caused by refraction. The optical path length through the atmosphere depends not only on the geometric path length, but also on the index of refraction of the air along that path. Fluctuations in the temperature, pressure and composition (primarily water vapor) of the air result in changes of the index of refraction and hence the delay. These variations in the index of refraction distort, as well as delay the stellar wavefront. These distortions are the cause of the SEEING which blurs the images made with a conventional telescope. The change in delay adds noise to the interferometric measurement.

This atmospheric noise is poorly behaved. It increases both with increasing baseline length and with increasing interval between observations. For extended observations of a single source, the accuracy of the measurement improves as the sixth root of the integration time, instead of the square root dependence typical of white noise.

The first consideration in dealing with this problem is the choice of baseline. For short baselines, the delay variations increase almost linearly with baseline length so the astrometric accuracy should improve very slowly with increasing baseline length. However, the size of the delay variations saturates when the baseline length reaches the outer scale of atmospheric turbulence. When the current flurry of optical interferometer construction began in the late 1980s, it was generally thought that the outer scale was very large so there was little advantage to using long baselines. However, since then, evidence has been steadily accumulating for outer scales at interferometric sites on the order of 30–100 meters. Longer baselines may indeed improve the accuracy of ground baseline astrometry.

If the air mismatch between the arms of the interferometer can be estimated, the observed delays can be corrected for the mismatch. This effectively reduces or eliminates the atmospheric noise. The correction is possible because the index of refraction of air increases toward shorter wavelengths with a known functional form. The delay variations are larger at blue wavelengths than at red wavelengths. This dispersion can be measured and is used to correct the observed delays for the atmospheric contribution. Specifically, over the visible spectrum, the index of refraction of air can be represented to high accuracy as a quadratic function of wavelength:

$$(n-1)_{\rm air} = n_0 + n_1\lambda + n_2\lambda^2. \qquad (4)$$

The delay can be represented by two terms; a vacuum delay, $d_{\rm v}$, which is the delay that would have occurred if there were no air; and the air mismatch, $L_{\rm air}$. Even though it is the index of refraction of air that is varying with time, not the actual air path, equation (4) provides a sufficiently good approximation to the problem. The optical path difference, OPD, is now a function of wavelength where $OPD = d_{\rm v} + (n-1)L_{\rm air}$. The fringe phase is given by

$$\begin{aligned}\phi &= \frac{2\pi}{\lambda} OPD \\ &= 2\pi[(d_{\rm v} + n_0 L_{\rm air})/\lambda + n_1 L_{\rm air} + n_2 L_{\rm air}\lambda]. \end{aligned} \qquad (5)$$

The first term depends on wavelength and represents the offset between the internal delay and the center of the fringe packet. The second term represents an offset between the center of the fringe packet and the white light fringe. The third term, the one containing n_2 causes a decrease in visibility for large air mismatches. As $L_{\rm air}$ increases, the central fringe is displaced from where it would have been in the absence of the air mismatch. The fringe packet is displaced by a different amount so a fringe is no longer centered in the fringe packet. By measuring both the position of the fringe packet and the offset of the fringe from the center of the packet, it is possible to solve for the air mismatch and the vacuum delay.

Since the water vapor content along the line-of-sight is not known, the coefficients used in equation (4) will not be exact. Nevertheless, they are known well enough and improvements in accuracy of a factor of 5 to 10 are routinely obtained. The wavelength dependence of the index of refraction produces a corresponding change in angle for observations with a transit circle, but this effect is too small to be exploited in a practical instrument.

Narrow angle astrometry

Restricting astrometric observations to a small portion of the sky results in higher precision astrometry since some systematic effects are common to all of the observations. These common effects shift the measured position for all the stars, but do not affect the measurement accuracy of the angles between the stars.

Delay fluctuations between two paths through the atmosphere increase as the separation of the paths increases. Figure 3 shows the observation of two stars separated by a small angle. If the separation, X, of the lines-of-sight at the distance of the turbulence is much smaller than the baseline, then the delay fluctuations between stars will be much smaller than the delay variations of either star separately. For this to work, the atmosphere must not change significantly between the observations of the two stars. For practical purposes, this means the stars must be observed simultaneously. For baselines on the order of 100 meters and stars separated by less than an arc minute, the measurements should be dramatically more accurate than wide angle measurements. Accuracies better than 100 microarcseconds, and possibly as good as 10 microarcseconds should be possible.

To achieve 10 microarcsecond accuracy on a 100 meter baseline, the differential delay between the two stars has to be measured with 5 nm accuracy—ten to one hundred times the accuracies required for wide angle astrometry. As a result, all optical paths in the system have to be measured with a metrology system.

Very narrow angle astrometry

The data in narrow angle astrometry is the same as it is in wide angle astrometry: the delay of the fringe as a function of time. When the separation of the two stars is so small that the fringe packets of the two stars observed on the same baseline overlap, a single detector can be used to observe both sets of fringes. In this case, the fringe amplitude becomes the observable. If the difference in delay between the two stars is zero, or an even number of wavelengths, the fringes from the two stars are in phase and strong fringe contrast is observed. However, if the delay difference is an odd number of half wavelengths, the fringes from the two stars are out of phase. The intensity from one star will be at a maximum when the other star will be at a minimum and the fringes will cancel, resulting in low fringe contrast. This is a simple example of measuring the spatial coherence to determine an image of the source. This type of observation is straightforward and is readily applied to measuring the orbits of binary star systems. Much has been published with the separations of the stars determined to an accuracy of 50 to 100 microarcseconds.

Bibliography

Detecting fringe phase with an optical interferometer and its usefulness for astrometry was demonstrated with a series of optical interferometers built on Mt Wilson, California. These were the Mark I, the Mark II, and the Mark III interferometers:

Intergalactic Medium

About half a million years after the big bang, the ever-fading cosmic blackbody radiation cooled below 3000 K and shifted first into the infrared and then into the radio, and the smooth baryonic plasma that filled the universe became neutral. The universe then entered a 'dark age' which persisted until the first cosmic structures collapsed into gravitationally bound systems and evolved into stars, galaxies and black holes that lit up the universe again. Some time between REDSHIFTS of 7 and 15, stars within PROTOGALAXIES created the first heavy elements; these systems, together perhaps with an early population of QUASARS, generated the ultraviolet radiation that reheated and reionized the cosmos. The history of the universe during and soon after these crucial formative stages is recorded in the all-pervading intergalactic medium (IGM), which is believed to contain most of the ordinary baryonic material left over from the big bang. Throughout the epoch of structure formation, the IGM became clumpy and acquired peculiar motions under the influence of gravity and acted as a source for the gas that becomes accreted, cools and forms stars within galaxies and as a sink for the metal-enriched material, energy and radiation which they eject. Observations of absorption lines in quasar spectra at redshifts up to 5 provide invaluable insight into the chemical composition of the IGM and the primordial density fluctuation spectrum of some of the earliest formed cosmological structures, as well as of the ultraviolet background radiation that ionizes them.

Cosmological reionization

At epochs corresponding to z~1000, the IGM is expected to recombine and remain neutral until sources of radiation develop that are capable of reionizing it. The detection of transmitted flux shortward of the Lyα wavelength in the spectra of sources at z~5 implies that the hydrogen component of this IGM was ionized at even higher redshifts. There is some evidence that the double reionization of helium may have occurred later, but this is still controversial. It appears then that substantial sources of ultraviolet photons were already present when the universe was less than 7% of its current age, perhaps quasars and/or young star-forming galaxies: an episode of pregalactic STAR FORMATION may provide a possible explanation for the widespread existence of heavy elements (such as carbon, oxygen and silicon) in the IGM, while the integrated radiation emitted from quasars is probably responsible for the reionization of intergalactic helium. Establishing the epoch of reionization and reheating is crucial for determining its impact on several key cosmological issues, from the role reionization plays in allowing protogalactic objects to cool and make stars to determining the small-scale structure in the temperature fluctuations of the cosmic background radiation. Conversely, probing the reionization epoch may provide a means for constraining competing models for the formation of cosmic structures and for detecting the onset of the first generation of stars, galaxies and black holes in the universe.

Intergalactic hydrogen density

The proper mean density of hydrogen nuclei at redshift z may be expressed in standard cosmological terms as

$$\begin{aligned}\bar{n}_{\rm H} &= (\rho_{\rm crit}/m_{\rm H})(1-Y)\Omega_{\rm b}(1+z)^3 \\ &= (1.1\times10^{-5}\ {\rm cm}^{-3})(1-Y)\Omega_{\rm b}h^2(1+z)^3\end{aligned}$$

where Y is the primordial He abundance by mass, $\rho_{\rm crit}=3H_0{}^2/8\pi G$ is the critical density, $\Omega_{\rm b}=\rho^{\rm b}/\rho^{\rm crit}$ is the current baryonic density parameter and $H_0=100h$ km s^{-1} Mpc^{-1} is the present-day Hubble constant. Standard NUCLEOSYNTHESIS models together with recent observations of deuterium yield Y=0.247±0.02 and $\Omega_{\rm b}h^2$=0.0193±0.0014. Thus,

$$\bar{n}_{\rm H} = (1.6\times10^{-7}\ {\rm cm}^{-3})\frac{\Omega_{\rm b}h^2}{0.019}(1+z)^3.$$

As some of the baryons had already collapsed into galaxies at z=2–5, the value of $\Omega_{\rm b}h^2$=0.019 should strictly be considered as an upper limit to the intergalactic density parameter.

Because of the overwhelming abundance of hydrogen, the IONIZATION of this element is of great importance for determining the physical state of the IGM. Popular cosmological models predict that most of the intergalactic hydrogen was reionized by the first generation of stars or quasars at z=7–15. The case that has received the most theoretical studies is one where hydrogen is ionized by the absorption of photons, H+$\gamma\rightarrow$p+e (as opposite to collisional ionization H+e$\rightarrow$p+e+e) shortward of 912 Å; that is, with energies exceeding 13.6 eV, the energy of the Lyman edge. The process of reionization began as individual sources started to generate expanding H II REGIONS in the surrounding IGM; throughout an H II region, H is ionized and He is either singly or doubly ionized. As more and more sources of ultraviolet radiation switched on, the ionized volume grew in size. The reionization ended when the cosmological H II regions overlapped and filled the intergalactic space.

Photoionization equilibrium

At every point in an optically thin, pure hydrogen medium of neutral density $n_{\rm HI}$, the photoionization rate per unit volume is

$$n_{\rm HI}\int_{\nu_{\rm L}}^{\infty}\frac{4\pi J_\nu\sigma_{\rm H}(\nu)}{h_{\rm P}\nu}\,{\rm d}\nu$$

where J_ν is the mean intensity of the ionizing radiation (in energy units per unit area, time, solid angle and

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

frequency interval) and h_P is the Planck constant. The photoionization cross-section for hydrogen in the ground state by photons with energy $h_{P\nu}$ (above the threshold $h_{P\nu}{}^L$=13.6 eV) can be usefully approximated by

$$\sigma_H(\nu) = \sigma_L(\nu/\nu_L)^{-3} \qquad \sigma_L = 6.3 \times 10^{-18}\ \mathrm{cm}^2.$$

At equilibrium, this is balanced by the rate of radiative recombinations p+e→H+γ per unit volume,

$$n_e n_p \alpha_A(T)$$

where n_e and n_p are the number densities of electrons and protons and $\alpha_A=\sum<\sigma^n v_e>$ is the radiative recombination coefficient, i.e. the product of the electron capture cross-section σ^n and the electron velocity ve, averaged over a thermal distribution and summed over all atomic levels n. At the commonly encountered gas temperature of 10^4 K, α_A=4.2×10–13 cm^3 s^{-1}.

Consider, as an illustrative example, a point in an intergalactic H II region at (say) z=6, with density $\bar{n}_H$=(1.6×10–7 cm^{-3})(1+z)^3=5.5×10^{-5} cm^{-3}. The H II region surrounds a putative quasar with specific luminosity $L_\nu=10^{30}(\nu_L/\nu)^2$ erg s^{-1} Hz^{-1}, and the point in question is at a distance of r=3 Mpc from the quasar. To a first approximation, the mean intensity is simply the radiation emitted by the quasar reduced by geometrical dilution,

$$4\pi J_\nu = \frac{L_\nu}{4\pi r^2}.$$

We then have for the photoionization timescale

$$t_{ion} = \left[\int_{\nu_L}^{\infty} \frac{4\pi J_\nu \sigma_H(\nu)}{h_P \nu}\, d\nu\right]^{-1} = 5 \times 10^{12}\ \mathrm{s}$$

and for the recombination timescale

$$t_{rec} = \frac{1}{n_e \alpha_A} = 5 \times 10^{16}\ \mathrm{s} \times \frac{\bar{n}_H}{n_e}.$$

As in photoionization equilibrium $n_{HI}/t^{ion}=n^p/t^{rec}$, these values imply $n_{HI}/n^p\approx10^{-4}$, that is hydrogen is very nearly completely ionized.

A source radiating ultraviolet photons at a finite rate cannot ionize an infinite region of space, and therefore there must be an outer edge to the ionized volume (this is true unless, of course, there is a population of UV emitters and all individual H II regions have already overlapped). One fundamental characteristic of the problem is the very small value of the mean free path for an ionizing photon if the hydrogen is neutral $(\sigma_L n^H)^{-1}$=0.9 kpc at threshold, much smaller than the radius of the ionized region. If the source spectrum is steep enough that little energy is carried out by more penetrating, soft x-ray photons, we have one nearly completely ionized H II region, separated from the outer neutral IGM by a thin transition layer or 'ionization front'. The inhomogeneity of the IGM is of primary importance for understanding the ionization history of the universe, as denser gas recombines faster and is therefore ionized at later times than the tenuous gas in underdense regions. An approximate way to study the effect of inhomogeneity is to write the mean rate of recombinations as

$$\langle n_e n_p \rangle \alpha_A(T) = C \langle n_e \rangle^2 \alpha_A(T)$$

(assuming T_A is constant in space), where the brackets are the space average of the product of the local proton and electron number densities and the factor C>1 takes into account the degree of clumpiness of the IGM. If ionized gas with electron density n_e filled uniformly a fraction $1/C$ of the available volume, the rest being empty space, the mean square density would be $<n_e{}^2>=n_e{}^2/C=<n_e>^2C$.

The IGM is completely reionized when one ionizing photon has been emitted for each H atom by the radiation sources and when the rate of emission of UV photons per unit (comoving) volume balances the radiative recombination rate, so that hydrogen atoms are photoionized faster than they can recombine. The complete reionization of the universe manifests itself in the absence of an absorption trough in the spectra of galaxies and quasars at high redshifts. If the IGM along the line of sight to a distant source were neutral, the resonant scattering at the wavelength of the Lyα (2p→1s; $h_P\nu_\alpha$=10.2 eV) transition of atomic hydrogen would remove all photons blueward of Lyα off the line of sight. For any reasonable density of the IGM, the scattering optical depth is so large that detectable absorption will be produced by relatively small column (or surface) densities of intergalactic neutral hydrogen.

Gunn–Peterson effect

Consider radiation emitted at some frequency ν_e that lies blueward of Lyα by a source at redshift z_e and observed at Earth at frequency $\nu_0=\nu_e(1+z^e)^{-1}$. At a redshift z such that $1+z=(1+z_e)\nu_\alpha/\nu_e$, the emitted photons pass through the local Lyα resonance as they propagate towards us through a smoothly distributed sea of neutral hydrogen atoms and are scattered off the line of sight with a cross-section (neglecting stimulated emission) of

$$\sigma[\nu_0(1+z)] = \frac{\pi e^2}{m_e c} f\ \phi[\nu_0(1+z)]$$

where f=0.4162 is the upward oscillator strength for the transition, φ is the line profile function (with normalization $\varphi\int\varphi(\nu)\, d\nu=1$), c is the speed of light and e and m_e are the electron charge and mass, respectively. The total optical depth for resonant scattering at the observed frequency is given by the line integral of this cross-section multiplied by the neutral hydrogen proper density $n_{HI}(z)$,

$$\tau_{GP} = \int_0^{z_e} \sigma[\nu_0(1+z)] n_{HI}(z) \frac{d\ell}{dz}\, dz$$

where $d\mathscr{l}/dz = cH_0^{-1}(1+z)^{-1}[\Omega_M(1+z)^3+\Omega_K(1+z)^2+\Omega_\Lambda]^{-1/2}$ is the proper line element in a Friedmann–Robertson–Walker metric and Ω_M, Ω_Λ and $\Omega_K=1-\Omega^M-\Omega_\Lambda$ are the matter, vacuum and curvature contributions to the present density parameter. As the scattering cross-section is sharply peaked around ν_α, we can write

$$\tau_{GP} = \int_0^{z_e} \sigma[\nu_0(1+z)] n_{HI}(z) \frac{d\ell}{dz}\, dz$$

In an Einstein–de Sitter ($\Omega_M=1$, $\Omega_\Lambda=0$) universe, this becomes

$$\tau_{GP}(z) = \frac{\pi e^2 f}{m_e H_0 \nu_\alpha} \frac{n_{HI}}{(1+z)^{3/2}} = 6.6\times 10^3 h^{-1} \frac{\Omega_b h^2}{0.019} \frac{n_{HI}}{\bar{n}_H} (1+z)^{3/2}.$$

The same expression for the opacity is also valid in the case of optically thin (to Lyα scattering) discrete clouds as long as n_{HI} is replaced with the average neutral density of individual clouds multiplied by their volume filling factor.

In an expanding universe homogeneously filled with neutral hydrogen, the above equations apply to all parts of the source spectrum to the blue of Lyα. An absorption trough should then be detected in the level of the rest-frame UV continuum of the quasar; this is the so-called 'Gunn–Peterson effect'. Between the discrete absorption lines of the Lyα forest clouds, quasar spectra do not show a pronounced Gunn–Peterson absorption trough. The current upper limit at $z_e\approx5$ is $\tau_{GP}<0.1$ in the region of minimum opacity, implying from equation (14) a neutral fraction of $n_{HI}/\bar{n}^H<10^{-6}h$. Even if 99% of all the cosmic baryons fragment at these epochs into structures that can be identified with quasar absorption systems, with only 1% remaining in a smoothly distributed component, the implication is a diffuse IGM which is ionized to better than 1 part in 10^4.

In modern interpretations of the IGM, it is difficult to use the Gunn–Peterson effect to quantify the amount of ionizing radiation that is necessary to keep the neutral hydrogen absorption below the detection limits. This is because, in hierarchical clustering scenarios for the formation of cosmic structures (the cold DARK MATTER model being the most studied example), the accumulation of matter in overdense regions under the influence of gravity reduces the optical depth for Lyα scattering considerably below the average in most of the volume of the universe, and regions of minimum opacity occur in the most underdense areas (expanding 'cosmic minivoids').

A clumpy IGM

Owing to the non-linear collapse of cosmic structures, the IGM is well known to be highly inhomogeneous. The discrete gaseous systems detected in absorption in the spectra of HIGH-REDSHIFT QUASARS blueward of the Lyα emission line are assigned different names based on the appearance of their absorption features (see figure 1).

The term 'Lyα forest' (LYMAN ALPHA FOREST) is used to denote the plethora of narrow absorption lines whose measured equivalent widths imply H I column densities ranging from 10^{16} cm^{-2} down to 10^{12} cm^{-2}. These systems, observed to evolve rapidly with redshift between $2<z<4$, have traditionally been interpreted as intergalactic gas clouds associated with the era of baryonic infall and galaxy formation, photoionized (to less than a neutral atom in 10^4) and photoheated (to temperatures close to 20 000 K) by an ultraviolet background close to the one inferred from the integrated contribution from quasars. Recent spectra at high resolution and high signal-to-noise ratio obtained with the *Keck* telescope have shown that most Lyα forest clouds at $z\sim3$ down to the detection limit of the data have undergone some chemical enrichment, as evidenced by weak, but measurable, C IV lines. The typical inferred metallicities range from 0.3% to 1% of solar values, subject to uncertainties of photoionization models. Clearly, these metals were produced in stars that formed in a denser environment; the metal-enriched gas was then expelled from the regions of star formation into the IGM.

An intervening absorber at redshift z having a neutral hydrogen column density exceeding 2×10^{17} cm^{-2} is optically thick to photons having energy greater than 13.6 eV and produces a discontinuity at the hydrogen Lyman limit, i.e. at an observed wavelength of $912(1+z)$ Å. These scarcer LLSs are associated with the extended gaseous haloes of bright galaxies near the line of sight and have metallicities which appear to be similar to that of Lyα forest clouds.

In 'damped Lyα systems' the H I column is so large ($N_{HI}\lesssim10^{20}$ cm^{-2}, comparable with the interstellar surface

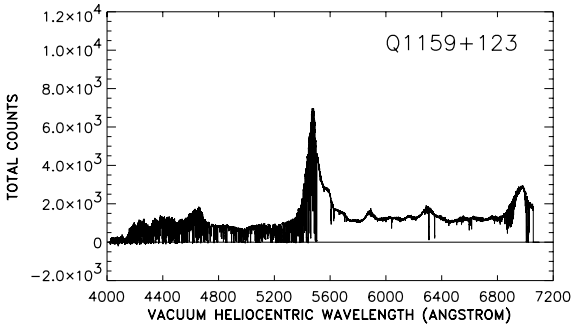

Figure 1. High resolution ($\lambda/\Delta\lambda=37\,000$) spectrum of the $z_e=3.50$ quasar Q1159+123, taken with the *Keck* High Resolution Spectrograph (exposure time 8 h). The data are taken from Songaila (1998). The Lyα forest is clearly seen in absorption blueward of the atomic hydrogen Lyα emission line from the quasar (the broad peak at 5470 Å) and is produced by resonant Lyα scattering in gas clouds along the line of sight between us and the quasar. The spectrum shows a Lyman-limit system (LLS) just shortward of 4150 Å, i.e. close to the quasar emission redshift. Most of the features between the Lyα and C IV emission (the other broad peak just below 7000 Å) are C IV intergalactic absorption lines.

density of spiral galaxies today) that the radiation damping wings of the Lyα line profile become detectable (see LYMAN ALPHA ABSORPTION: THE DAMPED SYSTEMS). While relatively rare, damped systems account for most of the neutral hydrogen seen at high redshifts. The typical metallicities are about 10% of solar and do not evolve significantly over a redshift interval $0.5<z<4$ during which most of today's stars were actually formed.

Except at the highest column densities, discrete absorbers are inferred to be strongly photoionized. From quasar absorption studies we also know that neutral hydrogen accounts for only a small fraction, ~10%, of the nucleosynthetic baryons at early epochs.

Distribution of column densities and evolution

The bivariate distribution $f(N_{\rm HI},z)$ of H I column densities and redshifts is defined by the probability dP that a line of sight intersects a cloud with column density $N_{\rm HI}$ in the range $dN_{\rm HI}$, at redshift z in the range dz,

$$\mathrm{d}P = f(N_{\rm HI}, z)\,\mathrm{d}N_{\rm HI}\,\mathrm{d}z.$$

As a function of column density, a single power law with slope –1.5 appears to provide at high redshift a surprisingly good description over 9 decades in $N_{\rm HI}$, i.e. from 10^{12} to 10^{21} cm^{-2}. It is a reasonable approximation to use for the distribution of absorbers along the line of sight:

$$f(N_{\rm HI}, z) = AN_{\rm HI}^{-1.5}(1+z)^{\gamma}.$$

Lyα forest clouds and LLSs appear to evolve at slightly different rates, with $\gamma=1.5\pm0.4$ for the LLSs and $\gamma=2.8\pm0.7$ for the forest lines. Let us assume, for simplicity, a single redshift exponent, $\gamma=2$, for the entire range in column densities. In the power-law model (16) the number N of absorbers with column densities greater than $N_{\rm HI}$ per unit increment of redshift is

$$\frac{\mathrm{d}N}{\mathrm{d}z} = \int_{N_{\rm HI}}^{\infty} f(N'_{\rm HI}, z)\,\mathrm{d}N'_{\rm HI} = 2AN_{\rm HI}^{-0.5}(1+z)^2.$$

A normalization value of $A=4.0\times10^7$ produces then ~3 LLSs per unit redshift at $z=3$ and, at the same epoch, ~150 forest lines above $N_{\rm HI}=10^{13.8}$ cm^{-2}, in reasonable agreement with the observations.

If absorbers at a given surface density are conserved, with fixed comoving space number density $n=n_0(1+z)^3$ and geometric cross-section Σ, then the intersection probability per unit redshift interval is

$$\frac{\mathrm{d}P}{\mathrm{d}z} = \Sigma n\frac{\mathrm{d}\ell}{\mathrm{d}z} = \Sigma n_0(1+z)^3\frac{\mathrm{d}\ell}{\mathrm{d}z}.$$

If the universe is cosmologically flat, the expansion rate at early epochs is close to the Einstein–de Sitter limit, and the redshift distribution for conserved clouds is predicted to be

$$\frac{\mathrm{d}P}{\mathrm{d}z} \propto (1+z)^3\frac{\mathrm{d}\ell}{\mathrm{d}z} \propto (1+z)^{1/2}.$$

The rate of increase of $f(N_{\rm HI},z)$ with z in both the Lyα forest and LLSs is considerably faster than this, indicating rapid evolution. The mean proper distance between absorbers along the line of sight with column densities greater than $N_{\rm HI}$ is

$$L = \frac{\mathrm{d}\ell}{\mathrm{d}z}\frac{\mathrm{d}z}{\mathrm{d}N} \approx \frac{cN_{\rm HI}^{1/2}}{H_0\Omega_{\rm M}^{1/2}2A(1+z)^{4.5}}.$$

For clouds with $N_{\rm HI}>10^{14}$ cm^{-2}, this amounts to $L\sim0.7h^{-1}\Omega_{\rm M}^{-1/2}$ Mpc at $z=3$. At the same epoch, the mean proper distance between LLSs is $L\sim30h^{-1}\Omega_{\rm M}^{-1/2}$ Mpc.

Intergalactic continuum opacity

Even if the bulk of the baryons in the universe are fairly well ionized at all redshifts $z\lesssim5$, the residual neutral hydrogen still present in the Lyα forest clouds and Lyman limit systems significantly attenuates the ionizing flux from cosmological distant sources. To quantify the degree of attenuation we have to introduce the concept of an effective continuum optical depth $\tau_{\rm eff}$ along the line of sight to redshift z,

$$\langle \mathrm{e}^{-\tau}\rangle \equiv \mathrm{e}^{-\tau_{\rm eff}}$$

where the average is taken over all lines of sight. Neglecting absorption due to helium, if we characterize the Lyα forest clouds and LLSs as a random distribution of absorbers in column density and redshift space, then the effective continuum optical depth of a clumpy IGM at the observed frequency ν_0 for an observer at redshift z_0 is

$$\tau_{\rm eff}(\nu_0, z_0, z) = \int_{z_0}^{z}\mathrm{d}z'\int_0^{\infty}\mathrm{d}N_{\rm HI}\,f(N_{\rm HI}, z)(1-\mathrm{e}^{-\tau})$$

where $\tau=N_{\rm HI}\sigma^{\rm H}(\nu)$ is the hydrogen Lyman continuum optical depth through an individual cloud at frequency $\nu=\nu_0(1+z)/(1+z_0)$. This formula can be easily understood if we consider a situation in which all absorbers have the same optical depth τ_o independent of redshift and the mean number of systems along the path is $\Delta N=\int dz\, dN/dz$. In this case the Poissonian probability of encountering a total optical depth $k\tau_o$ along the line of sight (with k integer) is $p(k\tau_o)=e^{-\Delta N}\Delta N_k/\tau_o k!$, and $\langle e^{-\tau}\rangle=e^{-k\tau_o}p(k\tau_o)=e[-\Delta N(1-e^{-\tau o})]$.

If we extrapolate the $N_{\rm HI}^{-1.5}$ power law in equation (16) to very small and large column densities, the effective optical depth becomes an analytical function of redshift and wavelength,

$$\tau_{\rm eff}(\nu_0, z_0, z) = \frac{4}{3}(\pi\sigma_{\rm L})^{0.5}A\left(\frac{\nu_0}{\nu_{\rm L}}\right)^{-1.5} \times (1+z_0)^{1.5}[(1+z)^{1.5}-(1+z_0)^{1.5}].$$

Because of the rapid increase with lookback time of the number of absorbers, the mean free path of photons at 912 Å becomes so small beyond a redshift of 2 that the radiation field is largely 'local'. Expanding equation (23) around z, one obtains $\tau_{\rm eff}(\nu^{\rm L})\approx0.36(1+z)^2\,\Delta z$. This

means that at z=3, for example, the mean free path for a photon near threshold is only Δz=0.18, and sources of ionizing radiation at higher redshifts are severely attenuated.

Recent observational results

NASA's Far Ultraviolet Spectroscopic Explorer (FUSE) satellite has given astronomers a glimpse of the ghostly cobweb of helium gas left over from the Big Bang, which underlies the universe's structure. The helium is not found in galaxies or stars but spread thinly through space. The observations help confirm theoretical models of how matter in the expanding universe condensed into a web-like structure pervading all the space between galaxies. The helium traces the architecture of the universe back to very early times. This structure arose from small gravitational instabilities seeded in the chaos just after the Big Bang.

International Astronomical Union

The mission of the International Astronomical Union (IAU), founded in 1919, is to promote and safeguard the science of astronomy in all its aspects. Through its 11 scientific divisions and 40 commissions, the IAU plays a key role in promoting and coordinating worldwide cooperation in astronomy. Strong emphasis is placed on personal involvement of its over 8300 individual members from 67 member countries. The IAU is integrated into the worldwide scientific community through its membership of the International Council for Science (ICSU).

The tasks of the IAU range from the definition of fundamental astronomical and physical constants and unambiguous nomenclature, rapid dissemination of new discoveries, organization of international observing campaigns, and promotion of educational activities in astronomy, to early informal discussions of possible future international large-scale facilities.

The IAU is also the sole internationally recognized authority for giving designations and names to celestial bodies and their surface features.

The organization of scientific meetings is a key activity. The triennial General Assemblies feature a rich scientific program, recorded in the 'Highlights of Astronomy'. The IAU also sponsors about a dozen carefully selected Symposia and Colloquia each year. Proceedings of these meetings are published under the auspices of the IAU as important records of the status of their scientific fields.

The IAU promotes astronomical education and research in developing countries through the International Schools for Young Astronomers and Teaching for Astronomy Development program, and through joint initiatives with other ICSU and UN organizations.

An IAU 'Information Bulletin' is published twice per year and distributed free of charge to individual members, adhering bodies, and astronomical institutes and libraries throughout the world. The IAU homepage on the Internet provides information and news from the Union and links to Divisions, Commissions, Working Groups and related organizations. The official languages of the IAU are English and French.

International Atomic Time

The international reference scale of time based on the continuous intercomparison of atomic times registered on numerous atomic clocks in laboratories and institutions around the world. Since 1971, international atomic time, which is denoted by the abbreviation TAI, has been provided by the Bureau International de l'Heure in Paris.

An atomic clock is a device that is regulated by reference to the natural frequency of a specific transition between two levels of a particular atom, usually cesium-133. The basis of atomic time is the SI (Système International) second, which is defined as 9192 631 770 cycles (periods of vibration) of the radiation corresponding to the hyperfine transition between two levels of the ground state of cesium-133. Because of small irregularities and changes in the rotation period of the Earth, time systems such as Universal Time (UT), which are based on the rotation of the Earth, differ very slightly from the much more uniform time-scale provided by atomic time. Since 1972, the time signals disseminated for civil use have been offset by whole numbers of seconds from TAI in order to keep these signals within 1 s of UT. The offset is changed in steps of 1 s when required. The adjusted atomic time-scale given by these signals is called Coordinated Universal Time and is denoted by UTC.

International Cometary Explorer (ICE)

NASA spacecraft, originally known as ISEE-3 (International Sun–Earth Explorer). First spacecraft to encounter a comet. Launched in August 1978. After completing its original mission, it was reactivated and diverted to pass through the tail of Comet Giacobini–Zinner on 11 September 1985. It also observed Halley's Comet from a distance of 28 million km in March 1986. (See also INTERNATIONAL SUN–EARTH EXPLORER and EXPLORER.)

International Space Science Institute

The International Space Science Institute (ISSI) was established in 1995 in Bern, Switzerland. Its main purpose is to provide a forum for the multidisciplinary analysis and interpretation of data from space research missions. The principal scientific focus is on solar system science and its implication for astrophysics and cosmology on one hand and for the Earth sciences on the other. The scientific activities are carried out through the organization of workshops on important scientific issues (twelve from its inception until 1999) and through international scientific teams of three to fifteen scientists, assembling at ISSI repeatedly for various periods of time. The scientific output is published in the ISSI Space Science Series of books (published by Kluwer Academic, Dordrecht), ISSI scientific reports (European Space Agency) and papers in scientific journals. Financial support is received in matching amounts from ESA and Switzerland.

International Ultraviolet Explorer (IUE)

NASA–ESA–UK ultraviolet observatory, launched in January 1978. Operated for 24 hours a day from geosynchronous orbit. Short and long wavelength spectrographic cameras covered ultraviolet wavelengths from about 1200 to 3400 Å. IUE observed planets, comets, novae, supernovae and galaxies. In July 1994 it observed the collision of Comet Shoemaker–Levy 9 with Jupiter. IUE provided confirmation of the nature of the precursor star which exploded as supernova 1987A, and revealed the chemical elements present in the star Nova Cygni 1978. Also took part in a major campaign to determine the nature of the mini-quasar at the centre of Seyfert galaxy NGC 7469. Provided a Final Data Archive containing more than 100 000 spectra. Operations ceased in September 1996. (See also EXPLORER)

Interplanetary Dust

The birth of a solar system is enshrouded in gas and dust. A collapsing rotating cloud increases in density until a critical point is reached and a YOUNG STELLAR OBJECT begins its rapid accretion at the center, still surrounded by a disk of gas and dust (figure 1). As stars evolve through a T-Tauri phase, much of this primordial dust cloud is removed by strong stellar winds and radiation forces. What remains may further accrete into planets and smaller bodies. Dust not accreted into larger bodies may find itself spiralling into the star by radiation drag or colliding with other particles, breaking up, and being ejected by radiation pressure.

By the time a star is as old as our Sun, no dust remains from those early years. Yet we find ourselves in a sea of dust, which we refer to as the zodiacal cloud or interplanetary dust complex. About one-third of other nearby stars are also surrounded by dust disks, though only one—Beta Pictoris—has been successfully imaged at the close of the 20th century (figure 2).

The zodiacal cloud is not primordial dust. Rather it is dust that has been generated, in the case of our own solar system, primarily by asteroid collisions and comet mass loss. Studies of the origin and nature of the zodiacal cloud provide insights into post-primordial dust production processes around other stars. Indeed, dust around other stars like ours is evidence for the existence of asteroidal and cometary bodies that would be too small to detect directly. The number of such systems is an indication of how common planet formation may be.

What is interplanetary dust?

This is a broad category of material which may range in size from submicron particles to automobiles. Basically, anything in orbit about the Sun which is too small to be a likely candidate for eventual individual designation as an asteroid or comet could be considered 'dust'—or better, interplanetary 'debris'. The particles can be of any composition as long as they are not artificial. The focus, however, is on the smaller members of this population.

History

Interplanetary dust can be seen with the naked eye in the morning and evening sky as a faint glow, brightest towards the Sun, extending and tapering along the ecliptic (figure 3). It can be comparable in brightness to the Milky Way. Since the zodiacal constellations lie along the ecliptic, this gave rise to the term 'ZODIACAL LIGHT' to describe the phenomenon. The 11th century Persian poet, astronomer and mathemetician, Omar Khayyam alluded to this 'false dawn' in his Rubaiyat. In 1683, Italian-born astronomer Gian Domenico Cassini 'discovered' the light in Europe (where inexplicably it had previously received no obvious note) and later ascribed it to a cloud of dust flattened on the solar equator, becoming brighter as one approached the Sun or its plane of symmetry. Under very good conditions, the zodiacal light can be traced completely

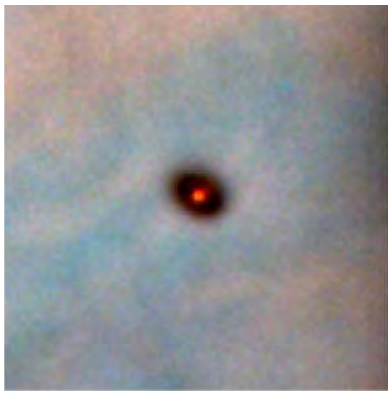

Figure 1. A protoplanetary disk and imbedded young star near the center of the Orion nebula, imaged by the Hubble Space Telescope.

across the sky, with a small increase in brightness at the anti-Sun position, which was named the 'Gegenschein' by the German naturalist and explorer Alexander von Humboldt in the early 19th century.

The existence of interplanetary dust having been established in one context (zodiacal light), it was in the late 18th and early 19th centuries when it was realized that this dust might be showering the Earth. The father of acoustical science, Ernst Chladni, argued for the extraterrestrial origin of METEORS, FIREBALLS and METEORITES in 1794. The spectacular Leonid meteor shower of 1833 (figure 4), and the observation that the meteors appeared to emerge from a stationary point in the constellation Leo, led many scientists of the day to independently conclude that these meteors were of extraterrestrial origin.

Near the end of the 19th century 'cosmic spherules' were collected from deep ocean sites and found to be chemically similar to meteorites. Analysis by E J Öpik of deep ocean samples collected in the 1930s suggested that the Earth was accumulating 8×10^9 kg of meteoritic material per year (or about 1.5 grams of material per square centimeter per year). If packed into a rock-like cube with a density of 3.5 g cm^{-3}, its dimension would be 132 meters. Dust collection experiments were conducted in ernest in the first half of the 20th century—often in scientists' back yards or on their rooftops. Rain and snowmelts were studied, generally involving magnetic separation of particles, and yielding nickel–iron particles which were presumed to be meteoritic. Estimates of the amount of material accumulated by the Earth over the course of a year varied by orders of magnitude, ranging from around 10^4 to 10^8 kg. Methods depended on meteor observations and meteorite falls as well as dust collection experiments. It was recognized that these estimates were necessarily incomplete. In the early 1950s, Warren Thomsen laid out several gallon cans lined with plastic on a farm several miles outside of Iowa City, and over a six month period examined the collected contents under a microscope. He estimated that magnetic, spherical, meteoritic dust fell at a rate of 2.0×10^9 kg/year over the entire Earth. This result (though ultimately within a factor of 2–4 of the later consensus value) sparked criticism which gave focus to concerns about the high potential for contamination of dust samples collected on the Earth's surface.

An effort was made to link dust collected on the Earth to dust observed in space. In 1947, van de Hulst estimated the mean mass density of interplanetary dust particles (IDPs) giving rise to the zodiacal light, taking into account light scattering properties of particles. Assuming this dust is swept up at the Earth's orbital velocity, the annual infall of dust would be 6×10^8 kg.

As new technologies became available, they were applied to the problem of identifying infalling interplanetary dust and to determine its properties. In the 1940s, radar was used to determine meteor velocities. Converted V2 rockets were launched with acoustical detectors to detect the sounds of small particles bouncing off the surface. The problems of contamination near the Earth's surface were solved with the advent of aircraft collectors by 1960 and the use of high-altitude balloons. Zodiacal light was increasingly studied photographically and with photoelectric photometers and polarimeters, but airglow, extinction and other atmospheric problems made this difficult. By the 1960s the zodiacal light could be observed from spacecraft. With better measurements of zodiacal light and better collections of extraterrestrial particles in the upper atmosphere of the Earth, the consensus value for the amount of dust accreted by the Earth each year became around 10^9 kg.

Table 1. Spacecraft studying interplanetary dust.

	Launch date	Heliocentric distance (AU)
Pioneer 8	1967	0.97–1.09
Pioneer 9	1968	0.75–0.99
HEOS 2	1972	1.0
Pioneer 10	1972	1–18
Pioneer 11	1973	1–10
Helios 1	1974	0.3–1
Helios 2	1976	0.3–1
Galileo	1989	0.7–5.3
Hiten	1990	1.0
Ulysses	1990	1.0–5.4
Cassini	1997	1.0–10

In the last third of the 20th century, spacecraft and orbiting infrared telescopes have dramatically increased our knowledge of the complexity of the interplanetary dust cloud. Beginning in the late 1960s, these particles were sampled directly in space via impact detectors (see table 1). The Pioneer 8 and 9 spacecraft detected small particles which seemed to come straight from the

Sun. These were designated β-meteoroids. In the 1970s, Pioneers 10 and 11 extended measurements of dust densities beyond the orbit of Jupiter. In the 1980s, the Infrared Astronomical Satellite, an orbiting telescope sensitive to thermal emission, discovered numerous spatial structures within the zodiacal cloud in the inner solar system (figure 5). In the 1990s, impact detectors on the Galileo and Ulysses spacecraft detected streams of dust orginating from the Jupiter system. In 1993, using information from the Ulysses dust experiment, Eberhard Grün and colleagues announced the first direct detection of interstellar dust grains within the solar system.

These observations have greatly expanded the issues that can be addressed through studies of interplanetary dust (and debris). Specific dust production mechanisms, such as asteroid collisions and cometary mass loss, can be constrained. The birth of METEOR STREAMS is observed. The dynamical evolution of dust from its source regions can be modeled and the effects of radiation forces and gravitational perturbations from other planets explored. The study of interplanetary dust now offers increased insights into the nature and evolution of ASTEROIDS, COMETS and other source objects.

To date we have been restricted to a vantage point wholely within the cloud, and mostly interior to the dust production regions of the solar system. This makes it impossible to directly observe the edges of the cloud, to determine its full extent and more easily study the interactions between the cloud and the interstellar environment surrounding it. It is also difficult to observe structures which overlap each other along our lines of sight. In the 21st century, small telescopes might be sent beyond the orbit of Jupiter to observe from the outside what appears to be primary dust production regions of the cloud we see from Earth and to measure the extended cloud beyond. In the meantime, the Earth continues to collect dust, meteors and meteorites, from which more science is extracted as their context continues to broaden, and in 2006 the Stardust mission will return to the Earth a sample of dust taken from the coma of a comet.

Composition and morphology

Unmelted interplanetary dust, collected in the upper atmosphere by aircraft and balloons and collected from Antarctic ice, exhibits a range of porosities from delicate 'fairycastle' structures to more compact forms (figure 6). Large particles are more likely to be heated to melting upon entering the Earth's atmosphere. These melted 'cosmic spherules' characterize particles extracted from lake bottoms and soil—primarily because the unmelted particles are difficult to distinguish from terrestrial materials.

Typical compositions of IDPs collected at the Earth are similar to primitive carbonaceous chondritic meteorites (e.g., CI, CM, CR), many with relative excesses of carbon. It is interesting that these meteorites are rare, representing less than 3% of recent meteorite falls. However, details of IDP minerology (particularly evidence of interactions between minerals and solar nebula gas) in the larger (50–500 μm) MICROMETEORITES collected from polar ice suggest that their origin may be more primordial than that of the CARBONACEOUS CHONDRITE parent bodies. This may or may not be the case for the smaller (10 μm) particles collected in the stratosphere.

Dynamics and evolution

To understand the origin of particles collected at the Earth's orbit or detected by spacecraft elsewhere in the solar system we need to understand the forces acting on particle orbits. It is the evolution of these orbits under these forces that gives rise to what we perceive as the zodiacal cloud.

There are four general mechanisms which can affect the orbit of a particle: radiation forces, gravitational perturbations by planets, the interplanetary magnetic

field and collisions. With the exception of gravity, the other forces depend on particle size and mass, with the result that the ultimate distribution of particles in the interplanetary dust cloud will depend upon the size and mass of the particles being discussed.

Radiation forces

As a particle orbits the Sun, it will absorb or scatter solar photons, thereby picking up a component of the photon's momentum away from the Sun. This radiation pressure diminishes the effect of the Sun's gravitational attraction. Its strength is generally described by the ratio β of radiation force to gravitational force. Since both forces diminish as the square of a particle's distance from the Sun, their ratio is the same throughout the solar system, and depends solely on physical properties of the particle: $\beta \sim Q_{\rm pr}/\rho s$, where $Q_{\rm pr}$ is a radiation scattering efficiency factor, ρ is the particle mass density, and s is its radius. Smaller particles are generally more sensitive to radiation pressure than larger particles because their surface-area-to-mass ratio is greater for a given density. However, there comes a point when smaller particles become transparent to a given wavelength of light, and the effect of radiation pressure is diminished. For particles in orbit around the Sun, this transparency begins to occur near a radius of 0.1 μm. Figure 7 shows β as a function of size for spherical particles of various compositions.

If an object is large enough, the effect of radiation pressure is minimal and β is near zero. A small particle, with non-negligible β, chipped off or emitted from a big object ($\beta \sim 0$) will move into a larger orbit in response to the effectively weaker pull of the Sun. If its β is greater than 1, it will be repelled by the Sun and escape the solar system. However, presuming that the particle is ejected from an object already in orbit about the Sun, a much lower β will be required for escape. Figure 8 shows the orbital paths of particles of different β's which are released from a circular orbit. Particles with $\beta < 0.5$ remain in the solar system.

Because of the finite speed of light, particles scattering or absorbing a solar photon will pick up a component of momentum which acts to slow them down that is proportional to v/c, where c is the speed of light and v is the component of particle motion perpendicular to the direction to the Sun. This is known as Poynting–Robertson (P–R) drag. Its effect is maximum at perihelion, where the particle's velocity is maximum. The result is that a particle's orbit will become more circular as it slowly spirals into the Sun. Both radiation pressure and P–R drag act only in the orbital plane of the particle. The timescale (in years) for P–R decay from a circular orbit at a heliocentric distance, R, is $T_{\rm pr} = 400R^2/\beta$. So even a fairly large object having a radius of 1 cm and density of 3 g cm^{-3} (hence $Q_{\rm pr} \sim 1$ and $\beta = 1.9 \times 10^{-5}$) that starts out in the asteroid belt at a heliocentric distance of 2.5 AU in a circular orbit will have fallen into the Sun after 130 000 000 years—a short time in comparison with the age

of the solar system. A 10 μm radius particle would take only 130 000 years. Thus, from radiation forces alone, a star's primordial interplanetary dust cloud would be lost on a fairly short timescale.

An interesting radiation force which acts primarily on particles large enough to sustain a temperature gradient from night to day is the Yarkovsky effect. The day side of an object will be warmer and hence emit a greater amount of thermal energy than the dark night side. Since radiation imparts momentum, the day side will feel a greater push away from the Sun than the night side feels a push towards the Sun. The net effect of this radial force on the object's orbit will be negligible. However, because of rotation and the fact that a warm surface takes a while to cool when it is no longer being heated, the evening terminator of the object will be warmer than the dawn terminator. This results in a force component which tends to either decrease or increase the orbital speed of the object, depending on its sense of rotation relative to its direction of motion. As a consequence of the Yarkovsky effect, an object between centimeters and tens of meters in diameter can be moved a significant fraction of an AU over many millions of years. This becomes even more important when combined with the effects of gravitational perturbations by planets.

Solar wind

The SOLAR WIND can also modify dust particle orbits analogously to radiation pressure and P–R drag. The solar wind is a fully ionized, magnetized plasma flowing nearly radially outward from the Sun. It is composed primarily of protons, electrons and alpha particles. The impact of the solar wind on dust particles has an effect that is negligible when compared to radiation pressure, but the 'corpuscular drag' force is about 30% that of P–R drag. This force becomes relatively more important as particles become small enough to be transparent to the solar radiation field. The particle cross sections to the solar wind continue to be described by geometric optics.

Gravitational perturbations by planets

Newton's law of gravity states that each object in the universe attracts each and every other body. The gravitational attraction of a dust particle is negligible, but the attraction of planets can be significant as a particle moves around the Sun. The effects of planets on particle orbits are greatest when a particle comes close to a planet and when it passes through a gravitational resonance. Resonances arise when the orbital motion of a particle is commensurable to that of a perturbing planet, causing an effect on the particle's orbit analogous to a forced harmonic oscillator. In some cases the particle's orbit becomes chaotic, changing wildly in eccentricity and inclination. Sometimes it can be 'trapped', its inward spiral interrupted for a time. This occurs in the vicinity of the Earth where dust is temporarily trapped in a resonant ring extending completely around the Earth's orbit (figure 9). The ring is not symmetric, having a region of higher density which trails the Earth as it moves around the Sun.

Dust interaction with the interplanetary magnetic field

UV radiation from the Sun, incident on a dust particle's surface, will release photoelectrons, resulting in the dust particle becoming positively charged. Equilibrium between the photoelectric current and the currents of the solar wind electrons and ions induces a surface potential of the order of a few volts positive. This causes the particle to interact with the magnetic field being carried away from the Sun with the solar wind. A particle orbiting the Sun

near the ecliptic will feel the resultant Lorentz force up or down, generally perpendicular to its orbital plane, as it travels through regions of different polarity, called sectors.

Collisions

In the asteroid belt, objects move with relative speeds of $\sim$5 km s^{-1}, when objects up to tens or hundreds of kilometers in diameter collide 'head on', they will be destroyed or 'catastrophically disrupted'. The mass of the original objects is redistributed into smaller fragments, dust and a small amount of vapor. When smaller dust particles collide the results are the same—mass is redistributed into smaller sizes. Some of the energy of collision goes into fragmentation and some into kinetic energy of the fragments. The latter causes some dispersion in the orbital elements of the fragments. The importance of this mechanism with respect to dust is that mass may be moved from sizes that are relatively insensitive to radiation forces to sizes that are very sensitive. Some amount of mass in 1 μm-sized particles will find itself on escape trajectories from the solar system. Also, some fraction of the fragments of debris having experienced numerous collisions may migrate from a relatively stable orbital position in the asteroid belt to a resonance region which puts them into Earth-crossing orbits.

Sources

The existence of a zodiacal dust cloud and the fact that particle orbits will ultimately decay under P–R drag necessitates a source or sources which replenishes the cloud we observe today. In the 20th century there was much discussion about potential sources of this dust. As more and more asteroids were being discovered, it was thought that the dust giving rise to the zodiacal light as well as METEOROIDS were just the small end of the asteroid size distribution. However, as methods were developed to determine the orbits of meteoroids prior to entering the Earth's atmosphere, it was discovered that many had high inclinations or large eccentricities, more similar to cometary orbits. Only four of 20 particles impacting early experiments on Pioneers 8 and 9 were determined to have asteroidal orbits. Consensus shifted to cometary sources. At the same time, however, estimates of dust produced by all comets fell far short of that felt necessary to generate the observed cloud. The situation was not improved until space-based observations in the thermal infrared revealed significant dust production directly related to both comets and asteroids.

Comets

Comets are known agglomerations of ice and dust. However, the dust we see in COMETARY TAILS is only a fraction of the refractory material comets release. The greatest mass of dust is lost in large particles. Unlike the micron-sized tail particles which stream away from the Sun by radiation pressure, millimeter to centimeter sized particles have low β values and move slowly away from the parent comet, tracing out a portion of the comet's orbit ahead of and behind the comet's position. This is a dust *trail*, the first stage in the evolution of a meteor stream (figure 10). These are not easily detected at visible wavelengths because comet refractory material is very dark. Because dark particles are warmer than lighter particles, the dark particles will be brighter in the thermal infrared—which is how cometary dust trails were discovered. One conclusion from studying these large comet particles is that comets are far rockier than previously thought, by factors of several. This gives comets dust-to-gas mass ratios comparable to that estimated for Pluto, at which distance these dust sources are thought to have formed.

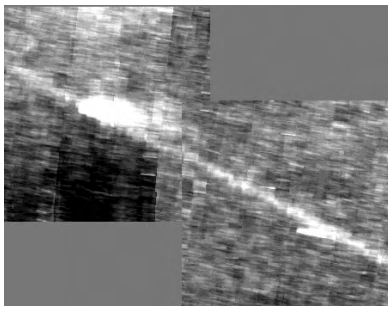

Figure 10. The most prominent dust trail in 1983 was associated with Tempel 2, appearing as a long narrow feature tracing out a portion of its orbit, ahead of and (primarily) behind the comet. Trails are the first stage in the dynamical evolution of meteor streams. They are the principal source of cometary dust contributed to the interplanetary dust complex. M Sykes, University of Arizona.

The cometary contribution to the zodiacal cloud is primarily due to short-period comets. Contributions to the zodiacal cloud from comets newly entering from the OORT CLOUD are small. Most dust particles released will escape the solar system, unless strongly perturbed by Jupiter or another planet into orbits which will retain them in the inner solar system.

Asteroids

Dust production by asteroids was first observed by IRAS (figure 11). IRAS observed bands of dust within the zodiacal cloud, which were associated with the major Hirayama asteroid families, Themis, Koronis and Eros. These families were sites of large disruptive events in the past in which a parent asteroid was shattered into a large number of smaller fragments. Continued disruptions of the smaller of these fragments by collisions with background asteroidal and cometary particles generate the dust we observe today. This process must be repeated throughout the asteroid belt, giving rise to the asteroidal contribution to the zodiacal cloud. While it is thought that the innermost bands, associated with the Themis and Koronis families, may be generating only 5% of the dust in the zodiacal cloud at present, their low inclinations result in their being a significant source of interplanetary dust particles at the Earth's orbit!

Figure 11. A map of the sky within 30° of the ecliptic plane constructed from IRAS scans high-pass filtered in latitude, showing dust bands (horizontal) encircling the inner solar system. These are associated with dust production within prominent asteroid families—sites of large past catastrophic collisions. Dark vertical bands indicate the areas not scanned during the third and final survey by IRAS which covered 75% of the sky. The angled lines and other noise-like features are associated with the plane of our Milky Way galaxy. M Sykes, University of Arizona.

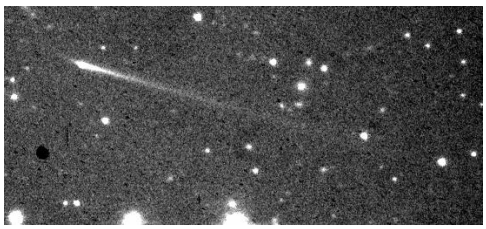

Figure 12. Analysis of the dynamical evolution of dust associated with the 'comet' Elst–Pizarro has led some to hypothesize that it is actually debris from a recent asteroid collision. C Hergenrother, University of Arizona.

Figure 13. An external view of the solar system in the thermal infrared with a spatial resolution of 0.2 AU at an angle of 30° above the ecliptic plane. The zodiacal cloud is simulated using a parametric model constrained by IRAS observations. To enhance the cloud, the image is logarithmically stretched. Jupiter is to the upper left. Earth and Mars are distinguishable to the left and right of the inner cloud, respectively. M Sykes, University of Arizona.

While the dust bands indicate the sites of ancient large collisional events, smaller dust-producing events are occurring in the asteroid belt all the time. Initially, debris from an asteroid collision would assume a distribution in space very similar to that of a comet dust trail. Differences in detail over time would arise due to the fact that the former is the result of a single event, while the latter is a more continuous process (by comparison). The discovery of 'comet' Elst–Pizarro in 1996 may have been one such example (figure 12). It had been detected in 1979, but was stellar in appearance with an asteroid-like orbit (low inclination and low eccentricity), so it was given a provisional asteroidal designation. Analysis of the dust seen in 1996 indicated a short outburst. Some analyses suggest a single event as would be expected for an asteroid collision.

One might hypothesize that if all asteroids are engaged in dust production via collisions then the radial distribution of dust through the asteroid belt should reflect the density of asteroids. To some extent this is true, and is reflected in the observations of the asteroidal dust bands. On the other hand, the orbits of the dust being generated decay under P–R drag, which acts to significantly smooth out local variations. This has been seen by the Ulysses spacecraft as it traveled through the asteroid belt, and swung around Jupiter back towards the Sun. The dust impact experiment on Ulysses indicated a relatively smooth distribution of dust flux from about the orbit of Mars to that of Jupiter. If this dust were dominated by asteroidal sources, it suggests that even the TROJAN ASTEROIDS (in a 1:1 resonance with Jupiter's orbit) are significant generators of dust.

Io

As the Ulysses spacecraft approached within approximately 1 AU of Jupiter, it began to detect streams of tiny particles ($< 0.1\ \mu$m) traveling at extremely high velocities ($> 200\ \mathrm{km\,s^{-1}}$). Analysis of these observations and later observations by the dust detector aboard the Galileo spacecraft showed that these particles originated from the volcanoes on Jupiter's moon Io (see IO: VOLCANISM AND GEOPHYSICS).

Interstellar space

Our solar system is traveling through the Milky Way in a direction that is different from the flow of a local interstellar cloud of gas and dust. As a consequence, dust particles penetrate the solar system and add to the interplanetary dust population, if only temporarily. These particles have been detected by the Ulysses, Galileo and possibly Hiten spacecraft. Their path through the solar system is complicated by gravitational focusing, radiation pressure and Lorentz forces, but there is still a discernable flow from the upstream direction of the interstellar cloud.

The shape of the zodiacal cloud

From the Earth, we are limited in our ability to discern the boundaries and large scale distributions of dust within our solar system, because we are looking from the inside

out. Two kinds of models have been developed to provide a picture of the cloud: parametric and physical. In a parametric model, we assume we know the functional form of the spatial distribution of particles. For instance, for a family of particles spiraling into the Sun by P–R drag, perhaps complicated by mutual collisions and Lorentz forces, the number density of particles would be expected to vary as r^{-k} where r is heliocentric distance. Some collision models and data from the Helios spacecraft suggest that the distribution of dust perpendicular to the ecliptic plane may be describable by a formula that looks like $\exp[-w(|z|/r)^t]$ where z is the distance from the ecliptic plane. The values of the parameters k, w and t are then determined by comparing predictions made by such a model with observations. Complexity can be increased by considering other reasonable conditions, such as the orientation of the cloud with respect to the ecliptic (after all, why should everything be exactly symmetric about the plane of the Earth's orbit?). Mathematically, the parametric model cloud stretches out to infinity in all directions (with decreasing density, of course). Viewed from outside the solar system such models generally provide uniform clouds, increasing in brightness rapidly as one approaches the Sun (figure 13).

With the discovery of the sources of zodiacal dust, the formation of the cloud itself can be simulated by considering those sources and modeling the dynamical and collisional evolution of those particles (figure 14). This is more realistic inasmuch as it deals directly with processes. We are still constrained, however, by the limitations of our observations within the inner solar system. Dust production is expected even beyond Neptune in the KUIPER BELT, through collisions. It is difficult to constrain such mechanisms without direct observations without the foreground contamination of local interplanetary dust.

A complex picture

At the beginning of the 21st century, one can no longer speak of 'interplanetary dust' in a monolithic fashion. The pieces of the puzzle that have been collected to date suggest that the composition and distribution of dust vary with size and location in the solar system. Throughout the inner solar system, the largest debris is probably asteroidal, but as we consider dust below a millimeter to centimeter in size, we would expect to see a significant increase in the contribution due to comets. This may in part offer an explanation for the difference in compositions between collected dust and meteorites at the Earth. However, the much larger fraction of 'primitive' carbonaceous material in micrometeorites may have more than one explanation. Such carbonaceous material is physically weaker than stony material, and asteroids composed of such weaker material may more easily generate dust through collisions in the main belt, which is then removed via P–R drag. Further, observations by Ulysses suggests significant dust production is occurring within the dark and carbonaceous Trojan asteroid population. There is mass fractionation of dust in the inner solar system, because small particles (not on escape trajectories) will spiral into the Sun more quickly than large particles. Because orbital decay times increase with increasing particle size, eventually collision timescales will be shorter. The result is that the largest particles or debris will tend to be found near their source locations in the asteroid belt and near comet orbits, and changes in their spatial distribution will be dominated by mechanisms such as gravitational perturbations—the mechanism by which meteorites are transported to Earth-crossing orbits. As we move away from the Earth's orbit we cross the resonant ring of dust which locally enhances a narrow range of particle sizes. As we move away from the plane of the ecliptic we would find that the composition of the asteroidal component of the dust reflects the composition of higher latitude asteroids.

The advent of space-based observations from telescopes and spacecraft has resulted in linking interplanetary dust directly to its sources, which include both asteroids and comets. The study of dust now provides a new means by which the nature and evolution of those sources can be explored. Better estimates of the physical composition of comets, and hence their formation locations, have been determined. Asteroid collision models now have a new constraint to reproduce. Dust production in our own solar system is the one bit of 'ground truth' we have in understanding how dust around other older stars is being produced today. Ultimately, it will provide us with our best insights into the formation and existence of small bodies in other solar systems.

Interplanetary Network

An interplanetary network is a collection of spacecraft, separated by large distances, equipped with γ-ray burst detectors. By timing the arrival of a burst at each pair of spacecraft, an annulus of possible arrival directions for the burst is derived. With three spacecraft, two possible arrival directions are obtained, corresponding to the two intersections of two annuli (figure 1). With four non-coplanar spacecraft, a unique arrival direction can be determined. The accuracy of the determination depends, among other things, on the separations between the spacecraft. Separations of the order of an astronomical unit or more can give accuracies in the tens of arcseconds range. In many cases, the individual detectors have no direction-finding capability. However, if one or more detectors in the network can determine even a coarse arrival direction, it is often possible to derive a unique location with a three-spacecraft network by eliminating one of the possible intersections.

Interplanetary networks have been in operation since 1977. The current (third) network began in 1991 and at present consists of the Ulysses, Mars Odyssey, Wind and HETE missions. In general the detectors on interplanetary spacecraft are small, and the burst detection rate is about one per week. However, the good location accuracy allows successful searches for γ-ray burst counterparts to take place.

Interstellar Absorption Lines

Various constituents of the gaseous interstellar medium absorb radiation from a background source at specific combinations of wavelengths. As a result, there may be one or more localized reductions of intensity (or outright gaps), often referred to as 'lines' (images of a spectrograph's entrance slit—see figure 1), when one views a spectrum of the source. This effect arises from the ability of individual atoms, ions and simple molecules in space to assume unique, well-defined states of excitation (see also SOLAR SPECTROSCOPY: ATOMIC PROCESSES). These states are created by specific combinations of the electron wavefunctions, the coupling of spins or angular momenta of subatomic particles and, for molecules, the additional excitation levels arising from various allowed modes of vibration and rotation of bonded atoms. A transition from a state of low excitation (for interstellar species, usually the lowest possible one) to a more energetic state is made possible by the absorption of a photon having an energy very close to the difference in energy of two levels. A change in the reverse direction results in the emission of a photon. Observations of either of these processes can reveal the amount, composition, general physical state and movement of the interstellar gaseous medium.

Our earliest indication of the existence of gases in space arose from evidence that some absorption lines in the spectra of stars were not produced by the outer parts of the stellar atmospheres, as is usually the case for most of the spectral features that can be seen (e.g. the FRAUNHOFER LINES in the spectrum of our Sun). This finding was first brought out by observations of the BINARY STAR δ Orionis reported in 1904 by J HARTMANN. He found that the absorption features from singly ionized calcium atoms (Ca II) did not exhibit the periodically changing Doppler shifts resulting from the stars' orbital motions (as revealed by other spectral features). Later, other observers noted that these lines were generally stronger for more distant stars, thus ruling out the explanation that the lines arose from gaseous envelopes around the binary systems or the extended atmospheres of unseen companion stars.

Figures 1 and 2 show an example of absorption lines from the doublet of neutral sodium (Na I) at wavelengths of 589.0 and 589.6 nm in the spectrum of the star 6 Cas. The multiple lines within each feature illustrate that different clouds of gas have different Doppler shifts, indicating that they are moving at slightly different velocities projected along the line of sight.

Atoms and molecules have many transitions between excited electronic levels well above the ground state, but such features never arise from interstellar gases because all of the species are in levels with the lowest possible energy[1].

[1] An exception is that some atoms can be found in excited fine-structure states within the lowest electronic level. The relative populations in these states can give important information on local physical conditions in the gas, since they are populated by collisions with other atoms, even at the low density of the interstellar medium; see figure 7.

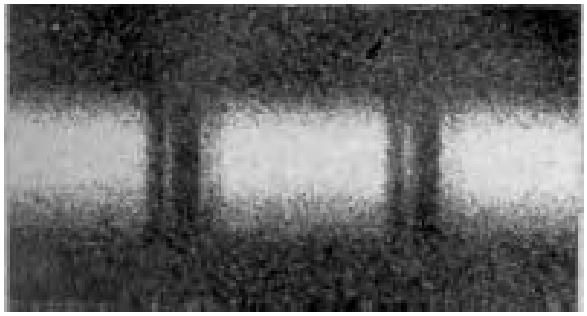

Figure 1. A print of the original photograph of a small portion of the spectrum of the star 6 Cas in the vicinity of the two D lines of neutral sodium. The intensity of starlight at successively longer wavelengths was recorded as a bright band spread from left to right, with vertical interruptions ('lines') caused by absorption from the intervening sodium atoms in space. (From Münch G 1957 *Astrophys. J.* **125** 42–65 © American Astronomical Society.)

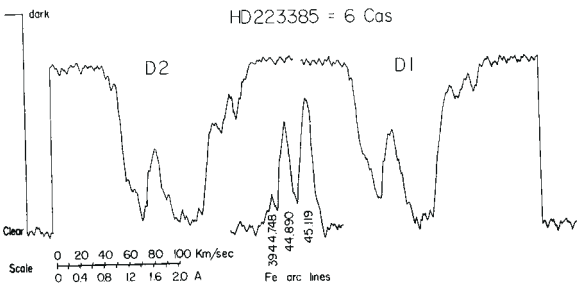

Figure 2. A densitometer tracing of the photographic exposure (hence 'dark' means a strong exposure level and 'clear' means little or no exposure) depicted in figure 1. The D2 atomic transition is twice as strong as the one for D1, and they are separated by 0.6 nm ($\equiv$6 Å on the scale shown at the bottom). Peaks and valleys within the D2 and D1 features are caused by absorbing clouds that have different Doppler velocity shifts. Emission lines from an iron arc are used to establish an accurate wavelength scale. (From the same source as for figure 1 © American Astronomical Society.)

By contrast, the atmosphere of a star has a large enough density and high enough temperature to create frequent collisional excitations with enough energy to populate the excited levels, thus leading to a much richer collection of spectral features.

A fundamental challenge in the investigation of interstellar lines is to separate them from the plentiful stellar lines. The easiest way to accomplish this is to observe only those stars that are rotating rapidly enough to make their lines wash out, owing to the superposition of many Doppler shifts from points on the star's surface that are moving at different radial velocities.

Constituents that can be observed at visible wavelengths and thus are available to ground-based, optical observatories include Ti II, Na I, Ca I, Ca II, K I, NH, CN, CH and C_2. In addition to these features, there are

more than 100 broad absorptions called diffuse interstellar bands that, for the most part, have origins that are poorly understood. These bands are detected only through significant accumulations of interstellar material, and it is generally acknowledged that they probably arise from complex, polyatomic molecules. It is clear that many types of molecules are involved, because different lines of sight exhibit features that have dissimilar relative strengths.

Unfortunately, all of the species identified with transitions in the visible part of the spectrum are minor ones, and, moreover, the atomic transitions (with one exception, Ti II) apply to stages of ionization that are not generally favored for most of the interstellar medium. Thus, while revealing the presence of gaseous matter and its motions, the lines in the visible part of the spectrum do not tell us much about the composition of the gas. Fortunately, other spectral regions offer much of the missing information. The ultraviolet part of the spectrum (91.2 nm–310 nm; see ULTRAVIOLET ASTRONOMY)[2] has a great abundance of strong lines from important atomic and molecular species, with many elements offering choices of features from several different degrees of ionization. The infrared and submillimeter regions (3 μm–1 mm) offer insights on the presence of many different molecules in dense interstellar clouds, with a number of transitions at wavelengths in the tens of centimeters (see INFRARED ASTRONOMY and MILLIMETER AND SUBMILLIMETER ASTRONOMY). These molecules can be seen in emission or, if there is a background continuum source, also in absorption. Finally, there is the very important (but very weak) transition of neutral hydrogen at a wavelength of 21 cm (or frequency = 1420.406 MHz) caused by a reversal in the alignment of the proton and electron spins (see RADIOASTRONOMY).

An overview of the composition of the interstellar medium is presented in INTERSTELLAR MATTER. Briefly, the most abundant chemical element in space is hydrogen, making up about 91% of all the atoms. Helium is the second most abundant element, and it accounts for nearly all of the remaining 9%. The heavier elements in the periodic table add up to only 0.13% of the total (by number of atoms, not by mass). Large fractions of many of the heavier elements have condensed into solids, in the form of small dust grains (see INTERSTELLAR GRAINS).

Within the disk of our Galaxy (the Milky Way) the average density of the gas is about 1 atom cm^{-3}, but there are enormous contrasts that range from about 10^{-3} atom cm^{-3}, where all of the atoms are ionized and very hot, to 10^4–10^5 atom cm^{-3} in cold clouds that are known from their emission lines in the radio to have complex molecules (see INTERSTELLAR MOLECULAR CLOUDS), or to even higher densities in regions that are collapsing to form stars. Over the distances to typical hot, luminous stars that can be seen by the unaided eye, a representative column of intervening atoms (mostly hydrogen) corresponds to a surface density in projection of about 3×10^{20} atom cm^{-2}. Put in terms of our everyday experience, this is equivalent to the number of air molecules at sea-level pressure and 0 °C in a column that is 11 cm long. For minor constituents that can be detected in optical or ultraviolet absorption lines, a typical detection limit for a stellar spectrum taken with a modern spectrograph that can give a high signal-to-noise ratio and good spectral resolution is of order 10^{10} atom cm^{-2}. Again using a terrestrial example, this is equivalent to the surface density of gold atoms contained within a column of sea water that is 1 cm long.

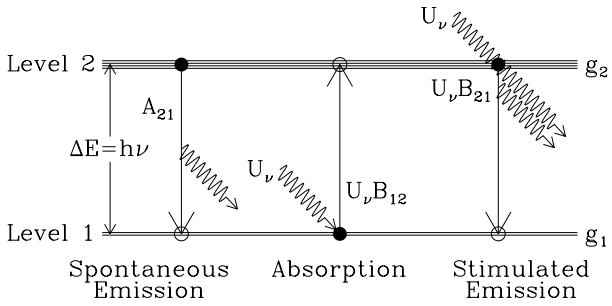

Figure 3. Three types of radiative interactions driven at rates A_{21}, $U_\nu B_{12}$ and $U_\nu B_{21}$ between two atomic levels separated by an energy difference ΔE. The statistical weights (number of degenerate quantum states within the levels) for levels 1 and 2 depicted here are $g_1 = 2$ and $g_2 = 4$. The Einstein coefficients A_{21}, B_{12} and B_{21} are related to each other in the manner shown by equation (1).

Fundamentals of radiative interactions

A single atom[3] interacts with radiation in three fundamental ways that were originally defined by EINSTEIN and are illustrated in figure 3. First, an atom in an excited level can decay to the lower state spontaneously and emit a photon with an energy $h\nu$ very nearly equal to ΔE, the energy difference between the two levels. The probability of this happening per unit time is given by the quantity A_{21}, a property of the radiative transition between the levels called the Einstein A coefficient (or transition probability). For transitions that are observed in interstellar studies, values for A_{21} range from 2.9×10^{-15} s^{-1} for the 21 cm transition of neutral hydrogen to a few $\times\, 10^9$ s^{-1} for the strongest UV lines between electronic excitation levels.

The other two modes of interaction, regulated by the rate coefficients B_{12} and B_{21} called the Einstein B coefficients, occur when the atom is exposed to a radiation

[2] Because the Earth's atmosphere is opaque to the UV radiation, these wavelengths must be observed by telescopes in orbit. The region below the Lyman limit at 91.2 nm is also useful in principle, but the intensities of all but the nearest stars in the sky are strongly attenuated by interstellar hydrogen atoms as they become ionized by the radiation. In the soft x-ray region, the opacity from hydrogen ionization is much lower. However, spectroscopic findings based on x-ray observations have been limited by the shortcomings of currently available instruments.

[3] Hereafter, for brevity, the term 'atom' is understood to mean a neutral atom, an ion or a molecule.

field. If photons with an energy $h\nu = \Delta E$ are present with an energy density U_ν (per unit frequency), transitions can be induced at a rate $U_\nu B_{12}$ from level 1 up to level 2. The absorption of the photon supplies the necessary energy for this to happen. The reverse of this process is also possible, i.e. a photon can induce an atom in level 2 to decay to level 1, and in so doing, a new photon is created that has the same frequency, phase and direction of the one that caused the event. This process, called stimulated emission, occurs at a rate $U_\nu B_{21}$. There are instances where ΔE is small and, as a result, there are enough atoms in the upper level to create enough stimulated emission to act as a negative absorption that partly cancels the normal absorption. This effect is significant for many transitions in the radio region.

The Einstein A and B coefficients are related to each other by the equation

$$g_1 B_{12} = g_2 B_{21} = \frac{c^3}{8\pi h\nu^3} g_2 A_{21} \tag{1}$$

where g_1 and g_2 are the statistical weights of the lower and upper levels, respectively. This relationship arises from the requirement that if the atoms were totally immersed in a hollow volume that had an interior radiation field with a Planck black body energy density distribution

$$U_\nu = \frac{8\pi h\nu^3}{c^3(e^{h\nu/kT} - 1)} \tag{2}$$

with a temperature T, they must establish level populations n_1 and n_2 consistent with a Boltzmann distribution:

$$\frac{n_2}{n_1} = \frac{g_2}{g_1} \exp\left(-\frac{\Delta E}{kT}\right). \tag{3}$$

That is, without any coupling to other process, the atoms must be in thermal equilibrium with the radiation field. This can only happen when the coefficients for the transitions satisfy equation (1)[4].

Since the lifetime of the upper state is finite, the uncertainty principle allows radiative processes to occur with photons that have energies $h\nu$ slightly different to ΔE. The relative response as a function of frequency ν is given by the Lorentz profile

$$\phi(\nu) = \frac{\gamma}{4\pi^2[(\nu - \nu_0)^2 + (\gamma/4\pi)^2]} \tag{4}$$

where ν_0 is the central frequency of the transition having a reciprocal mean upper state lifetime γ (not necessarily equal to A_{21} because other processes, such as collisions or other transitions, may shorten the state's lifetime even more).

Instead of having an atom inside a radiation bath with an energy density U_ν, we may think of an equivalent situation where the atom is exposed to a highly directed beam with a photon flux per unit area and frequency $N_\nu = cU_\nu/h\nu$. The atom's transition rate from level 1 to level 2 then becomes $(h\nu N_\nu/c)B_{12}$. If N_ν varies with ν, the rate becomes $(h\nu/c)B_{12}\int N_\nu\phi(\nu)\,d\nu$. It follows that the effective geometrical cross section of an atom to remove photons from a beam is simply

$$\sigma(\nu) = \frac{h\nu}{c}\phi(\nu)B_{12} = \frac{g_2}{g_1}\frac{c^2}{8\pi\nu^2}\phi(\nu)A_{21}. \tag{5}$$

Interpretations of the observations

By custom, representations of the strengths of transitions seem to differ for investigators who work with different spectral regions or types of transitions. Many radio transitions are expressed in terms of A_{21} defined above, but most of the molecular transitions have their strengths defined by the squared modulus of the dipole matrix element $|\mu|^2$ used for calculating transition probabilities of electric dipole transitions:

$$A_{21} = \frac{g_1}{g_2}\frac{64\pi^4\nu^3}{3hc^3}|\mu|^2. \tag{6}$$

For transitions in the visible and ultraviolet, it is customary to speak in terms of a quantity f, called the oscillator strength or sometimes just the f value. This quantity refers to the cross section of an atom (equation (5)), but expressed in terms of the outcome from a classical derivation of $\int\sigma(\nu)\,d\nu = \pi e^2/m_e c$ for an electron with a charge e and mass m_e that is bound in a harmonic potential. For most discussions in a context of absorption lines, the applicable f value is the one that goes from the lower to the upper state f_{12}, but the subscript is usually omitted. The alternative forms of equation (5) are

$$\sigma(\nu) = \frac{8\pi^3\nu}{3hc}|\mu|^2\phi(\nu) \tag{7}$$

and

$$\sigma(\nu) = \frac{\pi e^2}{m_e c} f\phi(\nu). \tag{8}$$

A collection of atoms having a differential number distribution $N(v)$ as a function of velocity v projected along the viewing direction will present a combined cross section

$$\sigma(v) = \frac{\pi e^2}{m_e c} f\lambda \int_0^\infty \phi(\nu)N[v + \lambda(\nu_0 - \nu)]\,d\nu \tag{9}$$

if all of them are in the lower level. (λ is the central wavelength of the transition, c/ν_0.) Generally, the Doppler shifts in frequency caused by velocities over the extent of $N(v)$ are very much larger than the line's natural width γ. Given that $\int_{-\infty}^{\infty}\phi(\nu)\,d\nu = 1$, we can simplify equation (9) to the form

$$\sigma(v) = \frac{\pi e^2}{m_e c} f\lambda N(v) = 0.026\,54\, f\lambda N(v) \tag{10}$$

if we ignore the small contribution to $\phi(\nu)$ from the low-level, broad Lorentz wings that are well beyond the

[4] The B coefficients are sometimes defined in terms of a radiation energy flux J_ν instead of energy density U_ν. These coefficients are equal to $4\pi/c$ times the ones described here.

frequency shifts due to Doppler motions. The explicit details of equation (9) are important only for very strong lines in the ultraviolet, which will be discussed later. In other applications, cross sections can simply be expressed in terms of either equation (10) or equations (5) and (7) with $\phi(v)$ replaced by $\lambda N(v)$.

If some of the atoms are excited to an upper level, the stimulated emission from this level reduces the cross section by a factor $1 - \exp(-\Delta E/kT_e)$, where T_e is the excitation temperature of the levels defined by the Boltzmann equation (equation (3)). An extreme example of this is with the 21 cm transition of neutral hydrogen. The levels have a separation $\Delta E/k = 0.068$ K, and the populations are very strongly coupled to the gas's kinetic temperature (of order 20–100 K) because collisions populate the upper level much more frequently than its radiative decay rate. Thus the net absorption is dependent on the very small difference between absorption and stimulated emission, giving an absorption coefficient that is proportional to $N(v)/T$. (An even more extreme example is sometimes observed for transitions of the OH radical ($\lambda = 18$ cm) or H_2O ($\lambda = 1.35$ cm), where some source of energy populates the upper level so that $g_1 n_2 > g_2 n_1$, making T_e negative, and the region becomes a maser radio source; see RADIO SOURCES.) For visible and UV transitions, n_2 is almost always equal to zero because the states undergo radiative decay so rapidly. When this is true, we can neglect stimulated emission.

So far, we have not yet addressed the issue of how the collective absorption by the N atoms that contribute to $\sigma(v)$ produces an observable attenuation of a beam of radiation. Consider that these atoms are distributed with a uniform density and confined within some volume that has a cross sectional area A perpendicular to the beam. As the radiation starts to traverse this volume, it encounters an infinitesimal fraction p of the atoms which block the beam and reduce its intensity $I(v)$ by a relative factor $p\sigma(v)/A$, i.e. $\mathrm{d}I(v)/I(v) = -[\sigma(v)/A]\,\mathrm{d}p$. The cumulative effect of successive encounters with the remaining fractions of atoms is found by integrating the expression

$$\int_{I_0(v)}^{I(v)} \frac{\mathrm{d}I'(v)}{I'(v)} = -\frac{\sigma(v)}{A}\int_0^1 \mathrm{d}p \tag{11}$$

which, in turn, leads to an exponential absorption law for the ultimate fraction of the radiant energy that is transmitted,

$$\frac{I(v)}{I_0(v)} = \mathrm{e}^{-\tau(v)}. \tag{12}$$

In this expression, the optical depth $\tau(v)$ is identical to $\sigma(v)$ with the understanding that $N(v)$ now denotes the number of atoms per unit velocity and per unit area in projection. (Henceforth, we will adopt this definition of $N(v)$ and work with the quantity $\tau(v)$.)

Generally speaking, $N(v)$ can be a complicated function that produces absorption profiles with fairly arbitrary shapes, such as those shown in figure 2. If the resolving power of a spectrograph is so high that no detail in the structure of the line is lost by blurring, one can derive $N(v)$ from an observation by inverting equations (10) and (12),

$$N(v) = \frac{m_e c}{\pi e^2 f \lambda}\ln\left[\frac{I_0(v)}{I(v)}\right] \tag{13}$$

and estimating $I_0(v)$ by interpolation of the flux on either side of the line[5]. This method is the ideal way to interpret an absorption line observation, but its accuracy can be compromised, sometimes seriously, if (1) the velocity structure in the line is not fully resolved by the instrument, (2) the intensity in some part of the profile is very near zero (as it is in the example shown in figure 2) or (3) either the reading that corresponds to a zero intensity or the level of the continuum intensity $I_0(v)$ is hard to measure.

For either of the first two reasons stated above, one may have an observation of generally good quality but not be able to obtain a direct measure of $N(v)$. We consider first the simplest case where the details in the velocity structure of a line are degraded, or in extreme cases completely lost, by an instrument with limited wavelength resolution. Here, the intensity profile I_λ (not $\tau(\lambda)$) is smoothed by a convolution with the instrument's response function $S(\lambda)$.

If the absorption at all wavelengths within the feature is so weak that the approximation

$$\tau(\lambda) \approx \frac{I_0(\lambda) - I(\lambda)}{I_0(\lambda)} \tag{14}$$

is valid to a needed level of accuracy, we can determine the total number of absorbing particles in projection along the line of sight, the column density $N_{\mathrm{total}} \equiv \int N(v)\,\mathrm{d}v$, by the relation

$$\begin{aligned} N_{\mathrm{total}} &= \frac{m_e c^2}{\pi e^2 f \lambda^2}\int \frac{I_0(\lambda) - I(\lambda)}{I_0(\lambda)}\,\mathrm{d}\lambda \\ &= \frac{1.13\times 10^{19}}{f\lambda_{\mathrm{nm}}}\frac{W_\lambda}{\lambda}. \end{aligned} \tag{15}$$

(This equation is an integral form of equation (13) with the approximation of equation (14) and the transformation $\mathrm{d}v = c\,\mathrm{d}\lambda/\lambda$.) The integral in equation (15) is called the equivalent width of a line and is usually expressed in wavelength units, i.e. W_λ. (λ_{nm} is the wavelength expressed in the units of nanometers and N_{total} is in atoms cm^{-2}.) A geometrical interpretation of W_λ is that it represents the width of a box that extends from the continuum level to zero intensity and has the same area as the space enclosed by the reduced (absorbed) intensity $I(\lambda)$ and the continuum level $I_0(\lambda)$. This concept is illustrated by figure 4 (but, in this depiction, for a line that is too strong for equation (15) to be valid). The value

[5] Almost all of the modern methods of detecting intensity use detectors that give a linear response. However, for a densitometer tracing of a photographic exposure, such as the example shown in figure 2, this is not true. One must measure the response of the photographic film to varying levels of illumination and then use this information to apply a correction to each of the film density (darkness) values in the spectrum.

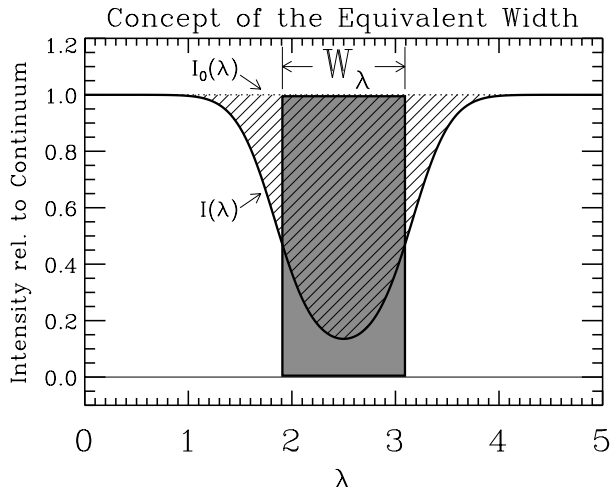

Figure 4. An illustration that demonstrates the concept of an equivalent width, as discussed in the text.

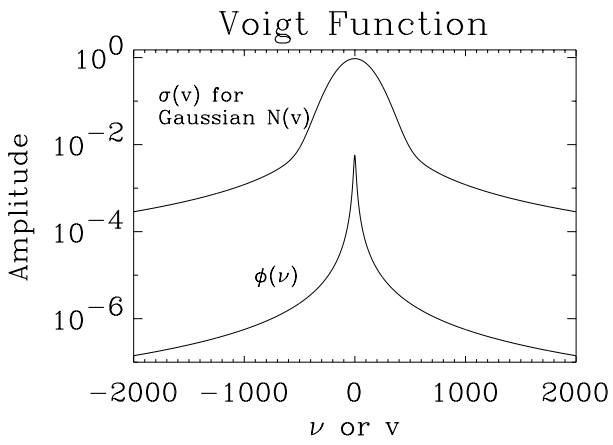

Figure 5. A semilogarithmic display of Voigt profiles for (lower curve) an atom at rest (giving the simple profile form $\phi(\nu)$ of equation (4)), compared with the combined effect of many atoms (equation (9)) having a Gaussian distribution of velocities (upper curve), as described in equation (16). Both scales in this representation are in arbitrary units.

of W_λ is unchanged by instrumental smoothing, making it a useful general property of a line and one for which we can obtain an answer for $N_{\rm total}$ that is not dependent on the instrument's $S(\lambda)$.

When a line becomes strong enough that it starts to become saturated, the approximation in equation (14) is no longer valid, and the linear relationship between N and W_λ expressed in equation (15) breaks down. A line with moderate saturation is illustrated in figure 4. If the line is well resolved by the instrument, we can go back to equation (13) and integrate it over velocity to obtain $N_{\rm total}$. If one has reason to believe that the line is not well resolved and is saturated, the value of N cannot be determined unless some assumptions are made or some independent information is available about the shape of the line.

A common practice is to assume that the line is formed by atoms that have a Maxwellian speed distribution, resulting in a velocity projected along the line of sight that follows the familiar Gaussian distribution centered at a macroscopic radial velocity v_0,

$$N(v) = \frac{N_{\rm total}}{\sqrt{\pi}b} \exp\left(-\frac{(v-v_0)^2}{b^2}\right) \tag{16}$$

where b is a velocity dispersion parameter (often called a b value or Doppler parameter). This assumption has its roots in the early, but usually mistaken, belief that the Doppler shifts are always dominated by the thermal motions of the atoms with $b = (2kT/m)^{1/2}$ (or perhaps turbulent motions that resemble thermal ones), rather than unpredictable macroscopic dynamical processes that could lead to profiles with very different shapes. Moreover, it overlooks the fact that one may be viewing a profile composed of multiple components, perhaps even superposed on each other (figure 2 is a good illustration of this situation). In spite of these shortcomings, the formalism is still very useful.

When $N(v)$ obeys the Gaussian form given in equation (16), the outcome for $\sigma(v)$ (or $\tau(v)$ for a column density representation of $N(v)$) in equation (9) is a Voigt profile. One example of this profile is depicted by the upper curve in figure 5. Its upper, parabolic portion (above 10^{-2} in this particular representation) gives optical depths that conform to equation (10) and is the only portion that can be detected for weak or moderately saturated lines. Only when the lines are exceptionally strong and saturated does one have a chance of seeing the effect of the broad Lorentz wings, as with the Lα and Lβ profiles in figure 6.

When the Voigt profile starts to become saturated, its equivalent width falls short of an extrapolation of the linear trend shown in equation (15). It now takes on the form

$$\frac{W_\lambda}{\lambda} = \frac{2bF(\tau_0)}{c} \tag{17}$$

where $F(\tau_0)$ is a special function of the line's central optical depth

$$\tau_0 = \frac{\pi^{1/2}e^2 f\lambda}{m_{\rm e}c}\frac{N_{\rm total}}{b} \tag{18}$$

given by

$$\begin{aligned} F(\tau_0) &= \int_0^\infty [1-\exp(-\tau_0\,{\rm e}^{-x^2})]\,{\rm d}x \\ &= \frac{\pi^{1/2}}{2}\sum_{n=1}^{\infty}\frac{(-1)^{n-1}\tau_0^n}{n!n^{1/2}}. \end{aligned} \tag{19}$$

(In the limit $\tau_0 \ll 1$, $F(\tau_0) = \sqrt{\pi}\tau_0/2$ and equations (17)–(19) reduce to equation (15).)

If one can measure W_λ/λ for two or more lines of different strengths from a particular atom, it is then possible to derive within this formalism the values of $N_{\rm total}$

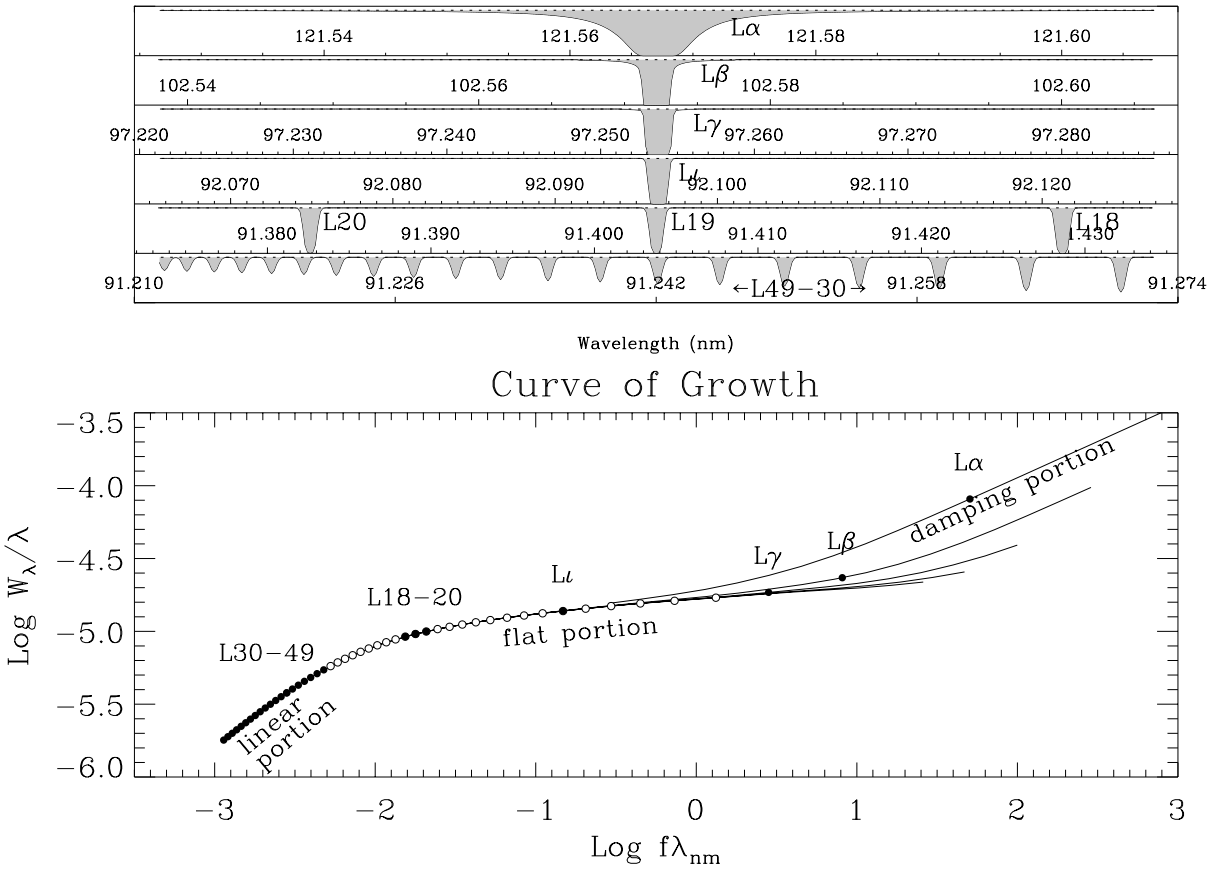

Figure 6. Selected line profiles in the Lyman series of hydrogen displayed over a radial velocity range of ±100 km s^{-1} (top panel) and a plot that shows where their equivalent widths occur on a curve of growth (bottom panel). In this example, $N_{\rm total}$(H I) = 2 × 10^{16} atom cm^{-2} and the velocity profile is a pure Gaussian (equation (16)) with b = 1 km s^{-1}. Different members of the Lyman series have different damping curves because their γ values are different (see equation (21)). (The condition that b = 1 km s^{-1} for hydrogen is an artificial one that was imposed to give the best demonstration of the principle of the curve of growth. Generally, interstellar or intergalactic hydrogen is observed to have $b > 10$ km s^{-1} when $N_{\rm total}$ is as low as 2 × 10^{16} atom cm^{-2}.)

and b by finding the best fit with a curve of growth[6]—a curve that takes on a universal shape for $\log(W_\lambda/\lambda) - \log(b)$ as a function $\log(N_{\rm total} f\lambda) - \log(b)$ for a Gaussian velocity distribution (equation (16)). Opportunities to perform such an analysis arise either from transitions that are completely unrelated or, alternatively, from a group of spectral features, called a multiplet, between a pair of electronic levels. The transitions in a multiplet are separated from each other by the slightly different energies that arise from different couplings of the electronic spins and angular momenta.

A curve of growth is illustrated in figure 6 for the Lyman series of atomic hydrogen[7]. Lines weaker than about L30 (only L30–L49 are shown) exhibit a nearly linear trend between W_λ/λ and $f\lambda$. The intensity profiles of lines that are found on the linear portion of the curve of growth (bottom sequence of features in the top panel of figure 6) approximately reflect an upside down representation of the shape of $N(v)$. As the transitions become stronger, their equivalent widths are described by equations (17)–(19) and their shapes become distorted into a more box-like profile. Lines in this regime are said to lie on the flat portion of the curve of growth. Finally, as the lines become exceptionally strong, the broad Lorentz (or damping) wings of the Voigt profile become evident and the equivalent widths reflect this additional contribution. Lines that exhibit this

[6] A misapplication of the curve of growth fitting with strongly saturated lines can lead to egregious errors in $N_{\rm total}$ (usually resulting in significant underestimates). This is especially true if narrow absorption features are hidden in a broad line whose equivalent width is dominated by a small amount of gas with a large value of b. In less extreme situations, such as a blended ensemble of lines with only mildly different bs and strengths, the underestimate in $N_{\rm total}$ that results from the oversimplification that there is a single component is relatively mild: it is usually of order 20% or less.

[7] The Lyman series is a progression of transitions out of the innermost (and lowest-energy) electron orbit of the atom. They lie between the ionization limit of hydrogen at λ = 91.25 nm and the Lα feature at 121.57 nm.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

property are said to lie on the damping portion of the curve of growth.

If the lines are completely dominated by the damping wings, the optical depth is given by the product of $N_{\rm total}$ and each atom's $\sigma(\nu)$ (equation (4) in the limit that $\nu - \nu_0 \gg \gamma/4\pi$ substituted into equation (8)):

$$\tau(\nu) = N_{\rm total} \frac{e^2 f \gamma}{4\pi m_{\rm e} c(\nu - \nu_0)^2}. \qquad (20)$$

By integrating this expression over all ν, it follows that

$$N_{\rm total} = \frac{m_{\rm e} c^3}{\lambda^2 e^2 f \gamma} \left(\frac{W_\lambda}{\lambda}\right)^2. \qquad (21)$$

If possible, one should try to identify the damping wing shapes to confirm that indeed equation (21) is the valid one to use, instead of equations (17)–(19) that might, instead, apply to a portion of the curve of growth that has about the same slope.

When some of the velocity structure in a profile is partly resolved by the instrument so that more information is present than just W_λ, one can invoke an approach that is more sophisticated than the curve of growth analysis. A model for $N(v)$ is constructed on the assumption that it can be approximated as the sum of separate Gaussian components, each with its own $N_{\rm total}$, v_0 and b. One then solves (or searches) for the best fit between the recorded data and the expectation

$$\frac{I(v)}{I_0(v)} = \exp\left(-\sum_{i=1}^{n} \tau_i(v)\right) * S\left(\frac{v\lambda}{c}\right) \qquad (22)$$

an expression that substitutes $\tau(v)$ for $\sigma(v)$ in equation (9) for each of the n components and uses the definition for $N(v)$ given in equation (16) ($*$ denotes convolution). This is usually done by varying the free parameters $N_{{\rm total},i}$, $v_{0,i}$ and b_i until a minimum χ^2 is found, indicating that the best fit has been achieved. A shortcoming of this method is that one may be forced to make an arbitrary choice between two or more solutions that have equally good fits with the data (and, likewise, the number n of possible components is a matter of judgment).

Insights derived from the lines

Lines in the visible part of the spectrum have been used to explore the kinematics of the interstellar material as well as to bring out the general statistical properties of small clumps of gas and how they are distributed in space. These studies have been facilitated by spectrographs with very high resolving powers, some being able to differentiate Doppler shifts that change the wavelength by only one part in a million. Observations of molecular features at visible wavelengths have given insights on the presence of a few simple diatomic species. Measurements in the infrared and radio parts of the spectrum have completed the picture for more complex molecules, usually residing in clouds that are too dense to view at ultraviolet and visible wavelengths.

A particularly noteworthy observation was the discovery by A McKellar in 1941 that CN molecules in front of the star ζ Ophiuchi had their excited rotational levels populated according to a Boltzmann distribution (equation (3)) for a temperature slightly below 3 K. The significance of this was not fully appreciated until the discovery of the cosmic microwave background radiation some 22 yr later (see COSMIC MICROWAVE BACKGROUND).

The UV spectrometer and telescope on the COPERNICUS (OAO-3) satellite that operated from 1972 to 1981 opened up an important spectral range that contained the Lyman series of hydrogen, strong lines of elements ranging from carbon to zinc in the periodic table and, perhaps most significant, the only means (at the time) for detecting molecular hydrogen—the most abundant molecule in the universe. From spectra obtained by Copernicus, we learned from the absorption features of five-times-ionized oxygen (O VI) about the presence of gases at temperatures of around 3×10^5 K (hotter gases with $T \sim 10^6$ K are revealed by a diffuse, soft x-ray background emission). We also discovered that the gas-phase abundances of various heavy elements are significantly reduced as they condense into solid form to create the dust grains. The relative completeness of this depletion is increased for lines of sight where the density is large, and elements that can form refractory chemical substances tend to be more depleted than ones that form more volatile compounds.

The launch of the HUBBLE SPACE TELESCOPE (HST) in 1990 started a new era in the investigation of absorption lines in the ultraviolet. Vast increases in collecting area and spectrograph resolution over those of previous orbiting observatories have significantly improved our ability to record spectra with better precision and over much greater distances (toward fainter objects). We can now gather many spectral elements simultaneously. This has been facilitated by advances in light detection technology, starting from zero-dimensional detectors on board Copernicus (scanning photomultiplier tubes), moving on to one-dimensional ones (linear arrays) on the first-generation instruments of HST and finally arriving at two-dimensional sensors on a second-generation instrument called the Space Telescope Imaging Spectrograph (STIS). Figure 7 shows a small segment of the spectrum of a star (one echelle spectrum order out of 53 obtained in a single exposure). The wavelength resolving power of this spectrum is 1 part in 200 000, a figure that allows us to discriminate Doppler velocity differences of only 1.5 km s^{-1}. To appreciate the the better information content provided by higher resolutions, one can compare the fine details and the velocity scales shown in this figure with those of figure 2. With the added capabilities of HST, we have been able to survey the abundances of elements with very low abundances, probe the interstellar abundances and conditions toward stars in the halo of the Galaxy and (at lower resolution) examine absorption features from gas systems associated with other galaxies, using some of the brightest quasars and active galactic nuclei as the background light sources.

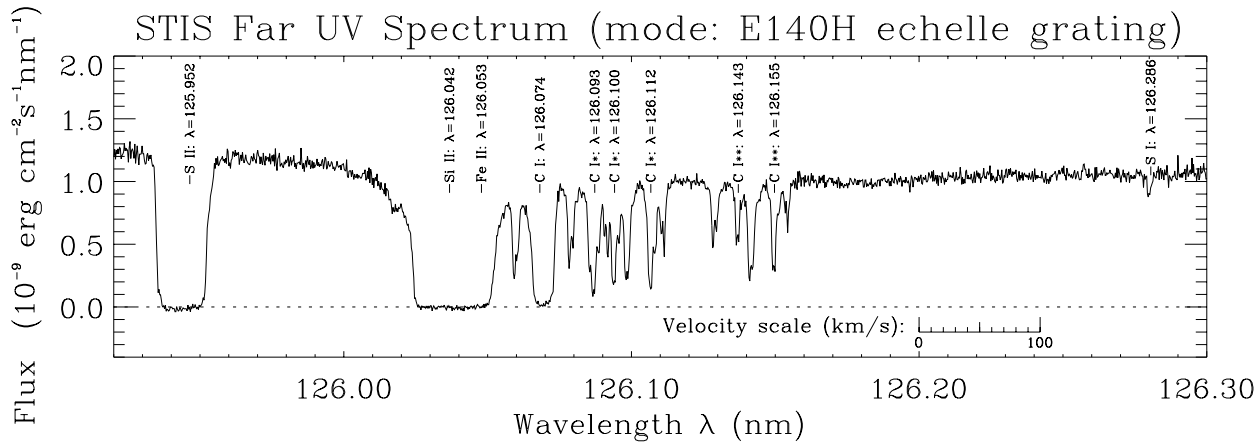

Figure 7. A small portion of the spectrum of the star λ Cep, recorded by the STIS on the HST, using a grating configuration that gave the highest resolution. Transitions are identified with markers aligned with the strongest velocity component at a velocity of -13 km s^{-1} in a heliocentric reference frame. For neutral carbon (C I), there are three main velocity components at -33, -13 and -3 km s^{-1}. Five out of the six C I transitions arise from two excited fine-structure levels in the ground electronic state (C I* is the first excited level and C I** the second one). The strengths of these features, relative to that out of the lowest level, indicate the local densities and temperatures of the gas where the carbon atoms are located. The wavelengths of the Si II and Fe II transitions are so close to each other that their absorption features overlap.

By virtue of the very large (Doppler) redshifts produced by the Hubble expansion of the universe, we can observe with large-aperture telescopes on the ground the UV transitions from distant gas clouds that are in front of even more distant quasars (see INTERGALACTIC MEDIUM and QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES). Intergalactic gas clouds of almost pure hydrogen were discovered by the numerous Lyman α absorption features that appear at wavelengths shortward of the quasar's red-shifted Lyman α emission feature (see LYMAN ALPHA FOREST). These clouds are mostly ionized, but they still contain enough neutral hydrogen to create conspicuous absorption features, including also the higher members of the Lyman series (shown in the very simplistic representations of the top panel of figure 6). Some sight lines to quasars penetrate foreground galaxies or their outermost fringes (see GALAXIES AT HIGH REDSHIFT). Such cases have given us opportunities to explore the character and composition of the gas in these distant systems, many of which cannot be seen in direct images.

Telescopes on the ground with apertures that range from 8 to 10 m in diameter are beginning to flourish. Working with modern, high-resolution spectrographs and sensitive electronic imaging devices (see SPECTROGRAPHS: HIGH-RESOLUTION SPECTROGRAPHS, CHARGE-COUPLED DEVICE), these new facilities will bring forth an abundance of superior observations of absorption lines that appear in quasar spectra and will tell us much about the evolution of gas systems through cosmic time.

Interstellar Chemistry

Molecules are not limited to the solar system but appear to exist throughout the universe. Interstellar chemistry is the study of molecular matter in interstellar space. It seeks to determine what the molecules can tell us about the physical conditions in the sources where they are detected and how the molecular matter is produced.

More than 25 yr of observational studies have shown that a rich variety of gas-phase molecules is associated with INTERSTELLAR MOLECULAR CLOUDS, which are vast regions of gas and tiny dust particles found among the stars in our Galaxy and others. A considerable number of molecules are also found in the extended atmospheres of certain classes of older stars. Molecules are detected in astronomical environments by comparing spectroscopic lines, in absorption or in emission, with known spectra in the laboratory. From the strengths and shapes of spectral lines, astronomers can deduce the concentrations of the molecules as well as the heterogeneous physical conditions prevailing in the sources. The existence of a solid interstellar phase consisting of dust particles of size ≈ 0.1 μm covered with a mantle of assorted molecular ices is inferred from the wavelength dependence of the scattering and absorption of visible light as well as from broad spectroscopic features. It is thought that interstellar molecules are formed locally, i.e. where they are detected, by chemical processes that can occur efficiently under physical conditions—very low temperatures and very low densities—quite different from those on Earth. Although our understanding is far from complete, the current state of knowledge of these chemical processes is sufficient to calculate correctly the abundances of many well-known interstellar molecules and to make accurate predictions for the abundances of others still unseen.

Interstellar molecules

The first gas-phase interstellar molecules—CH, CH^+, and CN—were discovered in the years 1937–1941 using the technique of optical absorption spectroscopy, a method which is only possible for so-called 'diffuse' interstellar clouds, which are sufficiently rarefied that stellar radiation can penetrate them. A far greater extent of molecular development is found in dense interstellar clouds, which have sufficient matter to extinguish the radiation of background starlight. Although the gas phase of such clouds contains approximately 99% of the matter, it is the dust particles that are responsible for most of the extinction. Dense clouds, which are sites of newly formed stars, are typically found in 'giant' complexes of material with higher-density objects (known as cores) embedded in lower-density material. The cores can contain protostars, which consist of warming, infrared-emitting, collapsing material in the act of forming new stars. Figure 1 shows a schematic view of a dense cloud complex.

Dense clouds have been studied primarily via RADIOASTRONOMY and, to an increasing extent, via INFRARED ASTRONOMY. Both techniques can be employed since wavelengths longer than visible wavelengths are extinguished to a diminished degree. In the gas phase, individual molecules undergo rotational and vibrational motions; the rotational–vibrational energies are quantized according to the laws of quantum mechanics. Transitions between rotational levels lead to spectra from the radio through the submillimeter-wave portion of the electromagnetic spectrum while transitions involving vibrational levels lead to spectra in the infrared region. Astronomers sometimes use the word 'radio' to apply to all wavelengths larger than infrared.

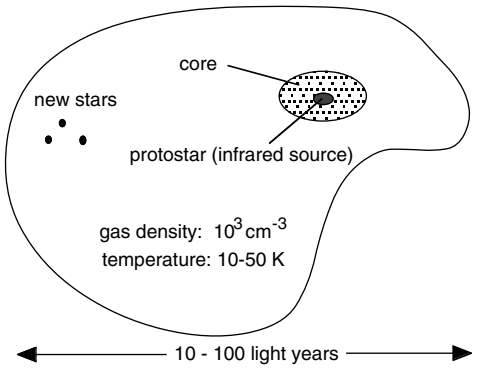

Figure 1. Schematic view of a dense interstellar cloud complex with some associated phenomena.

The first molecule detected by radioastronomical means was the diatomic species OH, which was found in 1963. The first polyatomic molecules—ammonia (NH_3) and water (H_2O)—were discovered in 1968 and the first organic (carbon-containing) polyatomic molecule—formaldehyde (H_2CO)—was detected soon thereafter. Since then, new molecules have been detected regularly every year, and there currently are known to exist over 100 gas-phase molecules consisting of up to 13 constituent atoms. These molecules are listed in table 1. (Some molecules in this table, classified as circumstellar, have been detected only in extended stellar atmospheres or both in these sources and in interstellar clouds.) In addition to these species, molecules containing isotopes such as deuterium, ^{13}C, and ^{18}O have been detected. In the last decade, infrared techniques have become increasingly powerful despite severe atmospheric interference, and a significant fraction of the molecules in table 1 have been detected in the infrared. Infrared detection is especially useful for non-polar molecules since such species do not possess strong rotational spectra. Although most 'radio' detections are observed over wide regions of clouds in emission, infrared detections are seen in absorption against background sources of radiation or against protostars forming in the clouds themselves. Much recent work in the infrared has been accomplished with the European infrared satellite called ISO (see INFRARED SPACE MISSIONS (INCLUDING ISO)).

The molecules listed in table 1 have all been detected under high spectral resolution. This fact, coupled with the detection of at least several lines for each species, makes the identification unambiguous except for a few species such as the simplest amino acid glycine (NH_2CH_2COOH), which are followed by question marks in table 1. The certainty of the assignments is important since the nature of the gas-phase molecules seen in interstellar clouds is very different from what chemists are used to on Earth. A glance at table 1 shows that most of the large molecules are organic in nature; this observation mirrors the relative numbers of inorganic and organic molecules known on Earth. On the other hand, the carbon-containing molecules in astronomical sources are often very unsaturated (hydrogen-poor), unlike naturally occurring species on Earth. Moreover, a large fraction of the interstellar molecules are not stable in the terrestrial laboratory because they are quite reactive. The unstable molecules include molecular ions (all but one positively charged), fragments known as 'radicals,' and metastable isomers, which are unusual geometrical arrangements of atoms. For example, HNC is an isomer of HCN, and c-C_3H is a cyclic isomer of linear C_3H, itself a rather reactive radical. It is because of the ingenuity of molecular spectroscopists, who have managed to take the spectra of many unusual species in the laboratory, that this witches' brew of interstellar molecules has been characterized. Although most of the molecules shown in table 1 have been found in clouds in our own Galaxy only, an increasing number have been found in external galaxies. In fact, simple molecules have been found in sources as distant as quasars and radiogalaxies with REDSHIFT $z > 4$.

Molecular spectra can be used for purposes other than the identification of individual molecules. From the relative intensities of the spectral peaks, relative concentrations, or 'abundances', can be determined. The abundances reflect both the relative amounts of elements available for incorporation into molecules and the chemical processes occurring in interstellar clouds. From studies of diffuse clouds, where the gas phase is mainly atomic, it is possible to determine elemental abundances that pertain to the gaseous interstellar medium. In general, these show that, compared with stellar atmospheres, heavy elements are partially depleted from the gas onto the dust grains. The depletion may or may not be greater in dense clouds. The abundances of heavy elements are also affected by the metallicities of galaxies. In the gas phase of a 'typical' interstellar cloud in our Galaxy, hydrogen is the dominant element, while the elements carbon, nitrogen and oxygen are lower by a factor of $\approx 10^{-4}$, with oxygen more abundant than carbon ('oxygen-rich' conditions). 'Carbon-rich' conditions, on the other hand, exist in certain stellar atmospheres.

Not surprisingly, the dominant molecule in dense interstellar clouds is molecular hydrogen, H_2. Whereas in diffuse clouds there is also a significant amount of hydrogen in atomic form, in dense clouds the hydrogen is almost completely molecular. One exception to this statement occurs in ionized regions around newly formed high-mass stars, where the hydrogen is mainly in its ionized atomic form. The second most abundant species in the gas—carbon monoxide (CO)—has a fractional abundance with respect to H_2 of $\approx 10^{-4}$ by number for typical dense clouds in our Galaxy, implying that this molecule consumes much of the available elemental carbon and oxygen. The fractional abundances of all polyatomic organic molecules with respect to H_2 are rather small; for example, that of methanol ranges from $\approx 10^{-7}$ to 10^{-10}. Despite their low fractional abundances, the total amounts of organic molecules in interstellar clouds are greater than corresponding amounts on the Earth. The molecular abundances in interstellar clouds do not reflect any equilibrium but are determined by rate processes. The positively charged species suggest an ionization source, and this is universally acknowledged to be COSMIC RAYS, which are chiefly high-energy protons. Such particles can ionize material directly or indirectly through the generation of ionizing photons.

From the point of view of many astronomers, the major use of molecular spectra from interstellar sources is the determination of the physical conditions and their heterogeneities in the sources. The rotational temperature of a molecule can be found from the relative intensities of differing spectral lines, and this temperature is related to the kinetic temperature of the source. The overall density of a source can be found from an analysis of the minimum density necessary to collisionally excite molecules which subsequently radiate; weakly polar molecules such as CO are easily excited and so appear at all densities above a low value whereas strongly polar molecules such as CS and HCN can only be detected in high-density cores where the collisional excitation is more rapid than the rapid rotational emission. In this manner, the low-density portions of dense cloud complexes have been determined to have gas densities $\approx 10^3$ cm^{-3} while the densities in the cloud cores range from $\approx 10^4$ to 10^8 cm^{-3}. Temperatures in quiescent cores, which show no dramatic signs of star formation, can be as low as 10 K, while temperatures in the more diffuse regions can rise to 50 K.

In addition to the narrow spectra, there also exist broad spectra from interstellar sources, the interpretation of which can be ambiguous. One such class of spectra derives from ices constituting INTERSTELLAR GRAIN mantles. The ices form in dense clouds as molecules condense onto the cold dust particles. Condensed-phase species tend not to show rotational spectra in the radio region because rotation is hindered by intermolecular forces. Condensed-phase species do undergo the same vibrational motions as gas-phase species. The vibrational spectra of molecules in the solid state are both broadened and shifted compared with the gas-phase values. The broadening and the shifting are sensitive to the local environment, so that these quantities can be used to characterize the nature of interstellar grain mantles. The most abundant molecule in the ice is water, which has a fractional abundance relative to gas-phase hydrogen of $\approx 10^{-4}$ by number. This high

abundance far exceeds what is found in the gas. Carbon dioxide (CO_2) is another well-characterized abundant surface species. Other molecules include CO, which is far less abundant than in the gas, as well as methane (CH_4), methanol (CH_3OH), ammonia (NH_3) and H_2S. The shape of the CO spectral line has been used to show that this species is found in two types of mantle environments—a polar and a non-polar one. Broad spectra also arise from a population of grain cores that consists of silicates, much like beach sand. A population of carbonaceous grains is inferred from a broad bump in the extinction of star light through diffuse clouds at 2200 Å, although whether this bump is due to graphite or amorphous carbon particles remains to be determined. Finally, emission from a planetary-nebula-type source known as the 'Red Rectangle' has been used to infer the existence of much smaller dust particles, known as nanoparticles, which consist of either carbonaceous or silicon-based material.

Not all broad spectral features originate from dust particles. A series of previously unidentified emission features throughout the infrared, known as the 'UIBs' or 'UIR' bands (standing for unidentified infrared bands), most probably arises from a collection of large molecules ($\geq$30 atoms in size) known as polycyclic aromatic hydrocarbons (PAHs), which are found terrestrially in automobile exhaust. Although no specific interstellar features can be identified with particular PAH species, it is likely that the broad interstellar spectra arise from a collection of PAHs with slightly differing vibrational frequencies and an overall fractional abundance with respect to H_2 of $\approx 10^{-7}$. An alternative interpretation in terms of small amorphous carbon particles exists.

Another series of broad features is seen in the visible, typically against the light of background stars, and presumably arises from diffuse interstellar clouds. These so-called 'diffuse interstellar bands' (DIBs; the word 'diffuse' is used to mean 'broad') have been known for

Dirac House, Temple Back, Bristol, BS1 6BE, UK

much of the century and have remained unassigned except for a few tentative possibilities. Following Sherlock Holmes' dictum that if one rejects the impossible, the improbable must be truth, investigators have considered the possibility that large gas-phase molecules can account for the lines and their large widths. The astronomical problem with this hypothesis is that small molecules are attacked by radiation, which is one reason that polyatomic molecules are not detected in diffuse clouds. It is possible, however, that very large molecules are relatively immune to photodestruction since they can store excess energy much like a heat bath. The spectroscopic problem with the hypothesis is that the molecules must heretofore have eluded laboratory detection. Most recently, five DIBs have been assigned to the negatively charged molecular ion C_7^-, which has been studied in detail in the laboratory within the last year. Another two lines may be due to the gaseous 'fullerene' ion C_{60}^+, although in the laboratory this species has only been studied in a solid matrix phase in which the vibrational spectral frequencies are displaced from the gas phase values. The remaining DIB problem is a large one; its eventual solution may yield surprising inferences about the state of interstellar matter.

Low-temperature chemistry

Although some molecules are formed in extended stellar atmospheres and blown out into space, the radiation field present in the unshielded interstellar medium is sufficient to destroy them long before they are incorporated into a dense molecular cloud along with other stellar detritus by the force of gravity. Large molecules such as PAHs, assumed to be formed in carbon-rich stellar atmospheres, and dust particle cores, observed to be formed in both oxygen-rich and carbon-rich stellar atmospheres, probably withstand photodestruction to a considerable extent. Thus, as interstellar clouds form, they are composed of a gas phase consisting mainly of atoms and a solid phase consisting of dust particles without ices. To produce the interstellar molecules of table 1 from atomic precursors requires an active local chemistry, which can occur both in the gas phase and on the surfaces of the dust particles.

The chemistry is severely constrained by the low density and temperature of the cloud, however dense it may be. The low density requires the gas-phase chemistry to consist of two-body collisions, since three-body collisions, by which is meant the collision of a third body with the temporary molecule formed by the collision of two other particles, are improbable. Temporary gas-phase molecules last for periods far less than 1 s while collisions in a gas of density $\approx 10^4$ cm^{-3} occur every $\approx 10^6$ s, or 1 week. Unlike the situation in the gas phase, dust particles can act as third bodies for reaction because atoms and molecules can stick to them. Consider a gas-phase species that lands on a dust particle and sticks to it with a certain efficiency. A second species then lands and sticks on the same grain, either atop the first species (Eley–Rideal mechanism) or elsewhere, in which case the two species must diffuse on the grain surface to find one another (Langmuir–Hinshelwood mechanism).

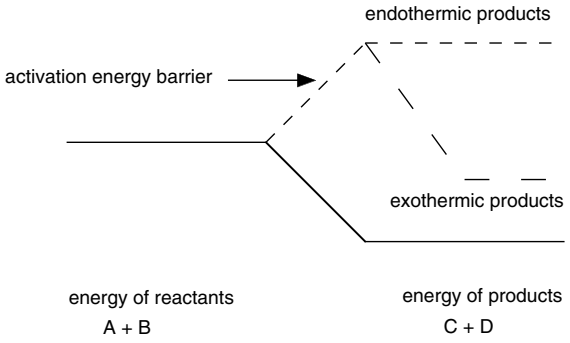

Figure 2. The energy profiles of three types of chemical reactions: endothermic, exothermic with activation energy and exothermic without activation energy.

The low temperatures remove from consideration both gas-phase and grain-surface reactions that require significant amounts of energy. These processes include all 'endothermic' reactions, in which the products lie at higher energy than the reactants, and those 'exothermic' reactions that require energy to overcome a potential barrier (the so-called 'activation' energy) occurring during the course of reaction even though the energy of products lies lower than that of reactants. See figure 2.

The rates of gas-phase chemical reactions are normally expressed in terms of thermal rate coefficients $k(T)$ and concentrations. For example, the rate of the reaction

$$\mathrm{A} + \mathrm{B} \longrightarrow \mathrm{C} + \mathrm{D} \tag{1}$$

is written as

$$\mathrm{d}n(\mathrm{A})/\mathrm{d}t = -\mathrm{d}n(\mathrm{C})/\mathrm{d}t = -k(T)n(\mathrm{A})n(\mathrm{B}) \tag{2}$$

where $n(I)$ stands for the concentration of species I. The thermal rate coefficient is related to the reaction cross section σ by

$$k(T) = \langle v\sigma \rangle \tag{3}$$

where v is the relative collision velocity between the reactants and the symbols $\langle \cdots \rangle$ stand for a thermal average over all degrees of freedom. In the limit of large numbers of reactive species on a grain surface, a rate equation treatment is appropriate for the diffusive (Langmuir–Hinshelwood) mechanism although the rate coefficients must incorporate a random walk or quantum mechanical tunneling motion rather than a simple relative velocity. In the limit of small numbers of reactive species on a grain surface, the rate equation method is problematic.

For endothermic reactions or for exothermic reactions with potential barriers, it is well known that

$$k(T) = A(T)\exp(-E_a/T) \tag{4}$$

where $A(T)$, the pre-exponential factor, can have a weak direct or inverse temperature dependence depending, for

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

gas-phase processes, mainly on the nature of the long-range potential and E_a, the activation energy, is written here in units of temperature. For most chemical reactions involving neutral species $E_a \geq 10\,000$ K so that, at typical interstellar cloud temperatures under 100 K, the rate of reaction is negligible. For reactions with smaller activation energies and light reactants, tunneling processes, not included in the above expression, can increase the rate coefficient at low temperatures, especially for processes on grain surfaces. Even so, interstellar chemistry is effectively limited to reactions with zero or small activation energy. In the gas phase, these include the following classes of exothermic processes: (i) reactions involving charged and neutral species, known as ion–molecule reactions, and (ii) reactions between neutral species in which at least one of the reactants is an atom or a 'radical', which is a particularly reactive molecule with an odd number of electrons. On the surfaces of grains, reactions of the second type must dominate since positive ions striking grains are thought merely to be neutralized by the excess negative charge present.

Ion–molecule reactions have been studied extensively in the laboratory down to low temperatures; they are known to occur with temperature-independent rate coefficients $k(T) \approx 10^{-9}$ cm^3 s^{-1} for non-polar neutrals and, for polar neutrals, with somewhat larger rate coefficients that increase weakly with decreasing temperatures. Gas-phase neutral–neutral reactions involving a radical are somewhat slower at room temperature, with a weak temperature dependence that is not fully understood. Very few studies of these systems at low temperatures have been undertaken. The products of all classes of reactions cannot be easily guessed at; rather, they must be measured or calculated via detailed quantum mechanical methods. For diffusive surface reactions, very few reactive systems have been studied in any detail, and estimates are often used for the rates of reaction.

The formation of interstellar molecules

Starting from atomic matter, it is difficult to form diatomic molecules in a low-density gas. Consider the collision of two hydrogen atoms to form a temporary hydrogen molecule, known as a 'complex'. This complex typically flies apart long before a third body approaches. There is a small chance that the complex can stabilize itself via the emission of a photon in a process known as 'radiative association', but this chance has been calculated to be remote for the association of two hydrogen atoms. Indeed, radiative association becomes efficient only for larger species. Although there do exist more efficient gas-phase syntheses of H_2 involving H^+ or H^-, it is now generally thought that interstellar H_2 is formed by diffusive recombination on dust grains and released back into the gas via both non-thermal and thermal processes, as depicted in figure 3. The recombination has been studied in the laboratory.

Once H_2 is formed, a complex gas-phase chemistry ensues in dense interstellar clouds; this chemistry

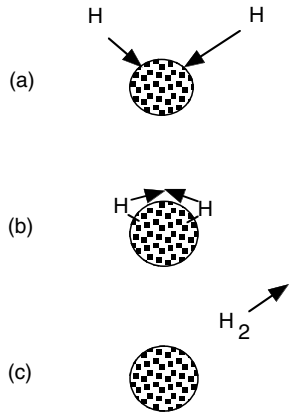

Figure 3. The formation of interstellar H_2 by a diffusive (Langmuir–Hinshelwood) process on an interstellar grain.

is dominated by positive ion–molecule reactions, but contains radical–neutral reactions as well. The ionization is typically provided by cosmic rays, which can penetrate through a total column density (concentration × path length) of more than 10^{25} cm^{-2}. The flux of cosmic rays, which are presumably formed in supernovae, is probably dependent on position within a galaxy and varies from one galaxy to another. Attempts to estimate this flux based on molecular observations are uncertain to an order of magnitude. The ionization provided is not great in a quantitative sense; both theory and observations of ions indicate that the fractional ionization is perhaps 10^{-7} with the largest uncertainty being the unmeasured metallic ion concentration. The small ionization is sufficient, however, to drive the ion–molecule chemistry. In diffuse clouds, the strong interstellar radiation field penetrates and provides a more potent source of ionization. The UV radiation is sufficiently energetic to ionize carbon, which possesses a rather low ionization potential, into C^+, leading to a factional ionization of $\approx 10^{-4}$. Even in diffuse clouds, however, ionization of hydrogen and helium requires cosmic rays.

Let us see how the initial stages of molecular synthesis work by considering the formation of water and simple hydrocarbons (molecules containing only carbon and hydrogen).

When a hydrogen molecule collides with a cosmic ray proton (CRP), the major products are the molecular ion and an electron:

$$H_2 + \mathrm{CRP} \longrightarrow H_2^+ + e^- + \mathrm{CRP}. \qquad (5)$$

The newly formed H_2^+ 'quickly' recombines with a neutral hydrogen molecule to form the simple polytomic ion H_3^+:

$$H_2^+ + H_2 \longrightarrow H_3^+ + H. \qquad (6)$$

This ion can react with different atoms present in the initial gas. The reaction with oxygen atoms is followed by a

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

sequence of reactions with ubiquitous H_2 leading to the rather stable protonated water ion:

$$O + H_3^+ \longrightarrow OH^+ + H_2 \quad (7)$$

$$OH^+ + H_2 \longrightarrow H_2O^+ + H \quad (8)$$

$$H_2O^+ + H_2 \longrightarrow H_3O^+ + H. \quad (9)$$

Not reactive with H_2, H_3O^+ eventually recombines with free electrons; recombination reactions are known to be dissociative in nature but only recently have experiments been able to determine the branching fractions among the various possible products. For the reaction between H_3O^+ and electrons, both the radical OH and the normal molecule water (H_2O) are products.

A similar sequence of reactions starting with atomic carbon leads to the methyl (CH_3^+) ion; this ion cannot react with H_2 in the normal manner but does undergo a rather slow but competitive radiative association reaction with hydrogen,

$$CH_3^+ + H_2 \longrightarrow CH_5^+ + h\nu \quad (10)$$

to lead to CH_5^+, which is a precursor of methane (CH_4) and methyl (CH_3).

Once simple molecules are synthesized, they are depleted via reactions with atomic and molecular ions and, in the case of radicals, neutrals. Photodestruction also plays a significant role, especially in diffuse clouds. Some of the depletion reactions lead to more complex species; others do not. Sequences of reactions leading to the production and depletion of most of the species in table 1 have been written down, although laboratory evidence for many of these processes is lacking. Occasionally, neutral–neutral reactions play important roles in the synthesis of molecules. Two examples, both studied in the laboratory at low temperature, are

$$C + C_2H_2 \longrightarrow C_3H + H \quad (11)$$

$$CN + C_2H_2 \longrightarrow HC_3N + H \quad (12)$$

these reactions produce the interstellar molecules C_3H and cyanoacetylene (HC_3N) more rapidly than do ion–molecule and dissociative recombination pathways.

Clearly, gas-phase chemistry does not represent the complete story. If molecular hydrogen is formed on grain surfaces, so must other species be. The production of molecules other than H_2 on grain surfaces is not well understood. It does appear that the dominant process is hydrogenation via hydrogen atoms which, although much less abundant than H_2 molecules in the dense cloud gas, are more reactive on surfaces and are able to hydrogenate species into rather saturated (hydrogen-rich) forms. The hydrogenation of atoms such as C, N and O into the saturated forms CH_4, NH_3 and H_2O via successive 'three-body' reactions with H is non-controversial, but the hydrogenation of molecular species such as CO into more hydrogenated molecules—H_2CO (formaldehyde) and CH_3OH (methanol)—is indeed controversial since small activation energies of uncertain amounts are involved. Although large amounts of hydrogenated species can probably be produced on grains, and are detected via infrared absorption studies, it is still unclear how some of these molecules get back into the gas phase since evaporation is too slow for all but the lightest species. Because the time scale for sticking to a dust grain is short compared with cloud lifetimes and because cold interstellar clouds are not devoid of gaseous material, there must exist non-thermal 'desorption' mechanisms such as heat generation by cosmic ray bombardment and by exothermic chemical reactions occurring on the grain surfaces.

Models of dense interstellar clouds

Chemical models of interstellar clouds date from the early 1970s. Such models are used to calculate concentrations of molecules as a function of time. To produce a time-dependent model, one integrates coupled differential rate equations, of the type shown in equation (2) but with both formation and depletion processes, for all species in the model. The initial concentrations and the elemental abundances to be used are constraints. The approach is only approximate for grain chemistry. Early models were steady state in nature, used only gas-phase reactions and did not involve the solution of simultaneous differential equations; rather, the concentration derivatives were set to zero so that the coupled equations could become algebraic in nature. Models of this type are able to explain the observed abundances of many of the smaller molecules.

After a decade of work and advances in computer technology, gas-phase pseudo-time-dependent models became available. In these models, coupled rate equations are solved but the physical conditions (temperature, density) remain fixed and uniform. The initial abundances are mainly atomic except for H_2. Such homogeneous models still represent the dominant approach today; these now contain thousands of gas-phase reactions connecting hundreds of molecular species. For the best-studied dense molecular cloud core, a quiescent core with gas density 10^4 cm^{-3} known as the Taurus Molecular Cloud 1 (TMC-1), pseudo-time-dependent models can produce order-of-magnitude agreement with observed abundances for up to 80% of the more than 50 detected molecules in the source. The time of best agreement depends on the gas-phase elemental abundances chosen, most specifically on the gas-phase carbon-to-oxygen abundance ratio. For oxygen-rich gas, the most complex of detected molecules are predicted to be abundant only at pre-steady-state times of $\approx 10^5$ yr, after which they tend to 'combust' into CO, much like the incomplete combustion that occurs in an old furnace.

Since gas-phase models ignore the contribution of grain chemistry to gas-phase abundances (other than to the formation of H_2), it is tempting to suggest that the synthesis of molecules with abundances not reproduced by such models can be ascribed to grain chemistry. Chemical models with both gas-phase and grain-surface reactions have been reported, but these

Dirac House, Temple Back, Bristol, BS1 6BE, UK

are still beset with uncertainties, including the correct mathematical approach and the role of surface chemistry in the production of species returned to the gas. Besides the absence of grain chemistry, other possible sources of error in gas-phase pseudo-time-dependent models include (i) uncertainty in the rates and products of gas-phase reactions, especially neutral–neutral processes and (ii) the assumption of homogeneous and time-independent physical conditions. More advanced gas-phase and gas-grain models, incorporating heterogeneous and changing physical conditions, have been reported. One particular approach is to utilize a number of slabs of different densities and temperatures; as one goes from slabs representing outer layers to slabs representing inner portions of the clouds, the densities become higher and the temperatures lower. Reality, unfortunately, is still more complex than this. There is good evidence that dense clouds have time-dependent self-similar structures on many distance scales down to clumps of stellar masses.

Recently, an interesting feature of gas-phase models, known as 'bistability', has been found. For selected choices of the parameters (density, temperature, elemental abundances), there exist not one but at least two solutions to the rate equations, labelled the 'low-ionization' and 'high-ionization' phases. Whether this bistability is an artifact of the models or whether it actually occurs in interstellar clouds remains to be determined.

Given the physical complexity of dense cloud complexes, it is important to note the major successes of simple gas-phase chemical models of cloud cores: (i) they predict the abundances of the major species (e.g. CO) and most minor species correctly, (ii) they account for the witches' brew (radicals, ions, metastable isomers) of unusual molecules present and the fact that the chemistry is mainly unsaturated (hydrogen-poor) despite the large abundance of H_2 and (iii) they account for very strong isotopic fractionation, particularly regarding deuterium, in which singly deuterated isotopomers (e.g. DCN) can have abundances approaching 10% of the normal species (HCN) despite the fact that the D/H elemental abundance ratio is only 10^{-5}.

The fractionation of deuterium is a thermodynamic effect made possible by the low temperatures. Consider the reaction of the ion H_3^+ with HD, the major repository of deuterium:

$$H_3^+ + HD \longrightarrow H_2D^+ + H_2. \qquad (13)$$

The reaction is exothermic by approximately 200 K owing partially to differences in the so-called zero-point energies of vibration between products and reactants. The reverse reaction, which is endothermic by this amount, cannot occur rapidly (see equation (4)) at temperatures significantly under 200 K because of the Boltzmann factor in the expression for the rate coefficient. If we neglect other reactions, equate the rates of the forward and backward reactions (as is appropriate at steady state) and make the assumption that the pre-exponential factors are the same, we obtain the following expression:

$$\frac{[H_2D^+]}{[H_3^+]} \approx \frac{[HD]}{[H_2]} \exp(200/T) \qquad (14)$$

where T is the temperature and the symbols $[\cdots]$ refer to concentration. Although not quantitative owing to the exclusion of side reactions and the assumption concerning the pre-exponential factors, the relation shows how the ratio $[H_2D^+]/[H_3^+]$ can become quite large at low temperatures. The high abundance ratio between the deuterated isotopomer and the normal species for H_3^+ and other molecular ions (e.g. HCO^+) then leads to the production of large abundances of deuterated neutral species through ion–molecule reaction chains. Isotopic fractionation also occurs on grain surfaces when high abundances of atomic D, generated from the dissociative recombination reactions of deuterated ions such as H_2D^+ and DCO^+ with electrons, adsorb onto the dust.

Current and future prospects

Much current work in interstellar chemistry pertains to distinctive regions surrounding sites of STAR FORMATION in dense interstellar clouds. Star formation is a complex process which gives rise to many physical manifestations in the surrounding material. The unusual physical conditions in turn give rise to chemical manifestations which are quite distinct from the ambient interstellar medium.

Sites of high-mass star formation are associated with shock waves and more quiescent dense regions called hot cores. The physics of shock waves is rather complex and is highly dependent on the size and direction of any magnetic field. In the limit of low magnetic field, there is a well-defined shock front which induces a rapid jump in temperature, depending on the square of the shock velocity. The temperature can rise to thousands of kelvins before subsequent cooling, so that a high-temperature chemistry can occur with endothermic reactions plus those exothermic reactions that contain activation energy. At sufficiently high shock velocities, molecular dissociation is manifest. Sputtering also occurs off dust grains, a process which is probably the only one to place refractory elements such as silicon into the gas phase. With a sufficiently large magnetic field, the temperature of the shock increases continuously in a more modest manner, and ions stream relative to the neutral species, powering otherwise slow ion–molecule reactions. In addition to their association with high-mass star formation, shocks are also found in the diffuse interstellar medium. Modelers have attempted to understand the shock chemistry in both diffuse and dense media, and have focused on those molecules the abundances of which constitute 'shock signatures'. In the diffuse medium, the molecule CH^+ has long been associated with shocks, where it can be formed by the strongly endothermic reaction

$$C^+ + H_2 \longrightarrow CH^+ + H. \qquad (15)$$

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Still, after much work, the importance of shock chemistry remains unclear. In diffuse regions, more attention is now being given to interstellar intermittent turbulence as a source for high-temperature chemistry.

Perhaps more successful have been chemical models of hot cores, which are quiescent regions of high density ($\approx 10^{6-8}$ cm^{-3}) and elevated temperatures ($\approx$100–300 K) in the vicinity of newly forming high-mass stars. In chemical models of hot cores, it is assumed that the rising temperatures drive material off grain mantles. Based on current ideas of grain chemistry, the desorbed molecules are thought to be mainly saturated (hydrogen rich) in nature, in good agreement with observations that show hot cores to have high abundances of simple species such as water and ammonia as well as more complex species such as the alcohols methanol (CH_3OH) and ethanol (C_2H_5OH), dimethyl ether (CH_3OCH_3) and methyl formate ($HCOOCH_3$). The original desorbed species undergo a gas-phase chemistry which takes $\approx 10^{4-5}$ yr to change the chemical composition and allows investigators to determine the ages of particular hot cores.

Sites of low-mass star formation are associated with protostellar disks, the chemistry of which is a current topic of considerable interest since radioastronomers are beginning to use interferometric methods to resolve such disks spatially and since the chemistry of these objects can be related to the chemistry of comets and planets in the initial stages of formation. These disks have higher densities than do ambient interstellar clouds but, unlike high-mass star formation regions, are characterized by low temperatures ($\leq$50 K) to within 10 AU (1 AU = mean distance between the Sun and the Earth) of the protostar. The high densities and low temperatures enhance the roles of grains and grain surface chemistry. Still, ion–molecule reactions are now known to be crucial because cosmic rays can penetrate through the plane of the disk at distances greater than a few AU from the protostar. Consequently, the chemistry bears some relation to that of the normal interstellar medium. Complications include the existence of an additional mode for ionization—radioactive decay—and the need to include three-body reactions for that portion of the disk closer than $\approx$10 AU to the newly formed star because of the especially high densities in the inner regions.

Although most observational and theoretical work on interstellar molecules has concerned our own Milky Way Galaxy, increasing emphasis in future work will shift to extragalactic studies. One can expect the chemistry occurring in different galaxies to have subtle and not-so-subtle differences from the chemistry in the Milky Way owing to factors such as varying ionization rates and metallicities as well as differing rates of star formation. Another field with potential for the future is the laboratory detection of unusual carbon-containing molecules that are likely candidates for interstellar detection. Several laboratories are currently working on both microwave and visible detection of such species.

In addition to increasing emphasis on the role of molecules as probes of diverse physical conditions and the synthesis of new and unusual molecules likely to be present in the interstellar gas, much research—both experimental and theoretical—will continue to be concerned with improving our understanding of the basic chemistry. For example, new experiments are being undertaken to simulate low-temperature grain chemistry, currently a large uncertainty in our understanding of the interstellar medium, and to simulate how large molecules such as PAHs can form in the gas phase. New theoretical techniques are being used to probe the chemistry involved in the formation of dust particles, and new approaches are being tried out to incorporate grain chemistry into chemical models. These and other efforts testify to a vigorous area of current research. Interstellar chemistry has been a major concern in astronomy for only 25–30 yr, but the role of molecules as probes of the cosmos and of our place in it will continue to intrigue many investigators in the future.

Interstellar Grains

Submicron solid particles are dispersed through interstellar gas. These *interstellar grains* absorb and scatter light, thus shielding some regions from ultraviolet radiation, but also limiting our ability to detect photons which have been emitted by astronomical objects. Dust grains re-radiate absorbed energy in the infrared, thus contributing to the overall emission spectrum of astronomical systems ranging from dusty disks around stars to ultraluminous starburst galaxies.

A naked-eye view of the sky from a dark site on a clear summer night reveals dramatic dark patches in the Milky Way. These dark regions are not due to a deficiency of stars—they are instead the result of obscuration by dust clouds interposed between the Earth and distant stars. The obscuration tends to be greater at shorter wavelengths; as a result, the light reaching us from distant, obscured stars is 'reddened'. This reddening by interstellar dust can be understood as arising from scattering and absorption by a population of interstellar submicron dust grains.

The grain population spans a range of sizes, from molecules[1] containing only tens of atoms to particles as large as ~ 0.3 μm, containing $\sim 10^{10}$ atoms. Most of the grain mass appears to be due to two types of solid, in approximately equal amounts: an amorphous silicate mineral and carbonaceous material. A number of elements—including silicon and iron—are primarily in solid form in the interstellar medium. Approximately two-thirds of the interstellar carbon in diffuse clouds is in solid form (see INTERSTELLAR ABSORPTION LINES).

It is of course important to characterize the wavelength-dependent interstellar extinction so that astronomical observations can be 'corrected' for the obscuring effects of dust. In addition, the infrared emission from dust grains provides a valuable probe of dense regions, and the dust grains themselves play important roles in interstellar chemistry (shielding from ultraviolet radiation, and catalysing the formation of H_2), interstellar gas dynamics (radiation pressure forces on dust grains, and coupling of charged dust grains to magnetic fields) and heating and cooling of interstellar gas. Dust grains are central to many problems in modern astrophysics.

Observational evidence: summary

There are many different astronomical phenomena which both reveal the existence of interstellar dust grains and provide information allowing us to infer the properties of this dust. Some of the information is quite direct, due to absorption, scattering, or emission of light by the grains:

(a) Wavelength-dependent extinction–attenuation and 'reddening' of the light from distant stars due to intervening dust (see figure 1).

(b) Spectroscopic features in the extinction. There are a number of extinction features, including: a strong

[1] Since all grains are 'molecules', it is natural to consider small molecules as the small-size end of the overall grain population.

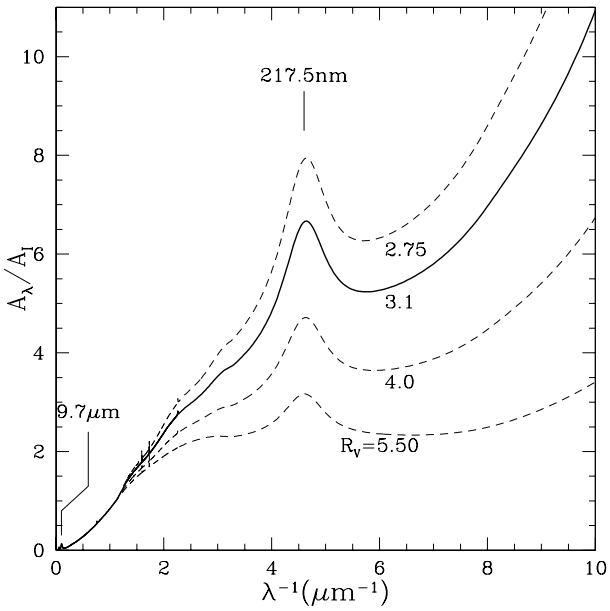

Figure 1. Wavelength-dependent extinction, normalized to the extinction at $I = 900$ nm, for different types of clouds, identified by the value of $R_V \equiv A_V/(A_B - A_V)$, where $V = 550$ nm and $B = 440$ nm. The average extinction for diffuse clouds is characterized by $R_V \approx 3.1$. Dense gas near the surfaces of molecular clouds can have R_V as large as 5.5. The extinction at I is approximately proportional to $N_{\rm H} = N({\rm H}) + 2N({\rm H_2}) + N({\rm H^+})$, with $A_I/N_{\rm H} \approx 2.6 \times 10^{-26}$ m^2/H.

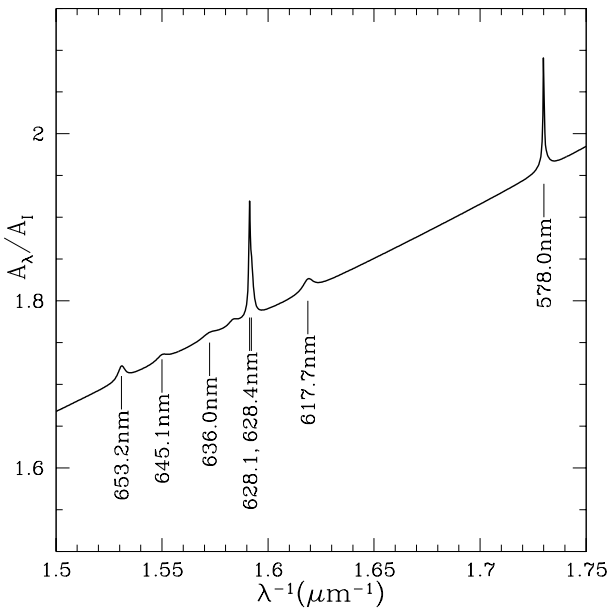

Figure 2. A portion of the extinction curve showing some of the 'diffuse interstellar band' extinction features, labelled with their respective wavelengths. These diffuse bands may be due to impurities in grains, or to 'free-flying' large molecules/ultrasmall grains.

and very broad extinction 'bump' at 217.5 nm (see figure 1), probably due to carbonaceous material, perhaps graphite; infrared extinction features at 9.7 μm and 18 μm, almost certainly due to silicates; a number of weaker 'diffuse interstellar bands' (see figure 2), the strongest of which are at 443 nm and 578 nm, and which remain generally unidentified; an absorption feature at 3.4 μm, seen in diffuse clouds, presumably due to the C-H stretching mode in aliphatic hydrocarbons; and a number of absorption features, seen only in molecular clouds, due to ice mantles which apparently coat the grains in these regions. The strongest such feature is a 3.1 μm feature attributed to H_2O ice.

(c) Polarization of starlight—preferential attenuation of one linear polarization over another by aligned interstellar dust grains, so that initially unpolarized light from a star is partially polarized by the time it reaches the Earth (see POLARIZATION).

(d) Reflection nebulae—dust clouds which are relatively close to bright stars, so that the starlight reflected by dust grains near the cloud surface renders the cloud visible (see REFLECTION NEBULAE).

(e) X-ray haloes around x-ray point sources located behind interstellar dust clouds. The haloes result from small-angle scattering of x-rays by interstellar dust grains.

(f) Infrared emission from dust grains heated by interstellar starlight (see figure 3).

(g) Infrared emission features indicative of aromatic hydrocarbons. The strongest features from the general interstellar medium are at 11.3 μm, and 7.7 μm (see figure 3).

(h) Emission features at 18 μm and 9.7 μm, generally thought to be due to silicates, from dust in regions with radiation fields $\geq 10^4$ times stronger than the average starlight background.

(i) There is strong evidence for emission from interstellar grains in the far red, presumably fluorescence following absorption of a shorter-wavelength photon.

(j) In the local interstellar medium, the dust-to-gas ratio appears to be approximately constant—the dust follows the gas.

Although limited, we also have some quite direct evidence concerning interstellar grains:

(a) Relic interstellar grains found in primitive 'carbonaceous chondrite' meteorites.

(b) Impacts with interplanetary probes of interstellar grains passing through the solar system.

In addition, there are a number of astrophysical phenomena which provide indirect information about interstellar grains:

(a) Underabundances, relative to solar abundances, of certain elements in interstellar gas—including iron, silicon, magnesium, and carbon. These elements are presumed to be underabundant in the gas phase because a large fraction of the atoms are locked up in interstellar grains.

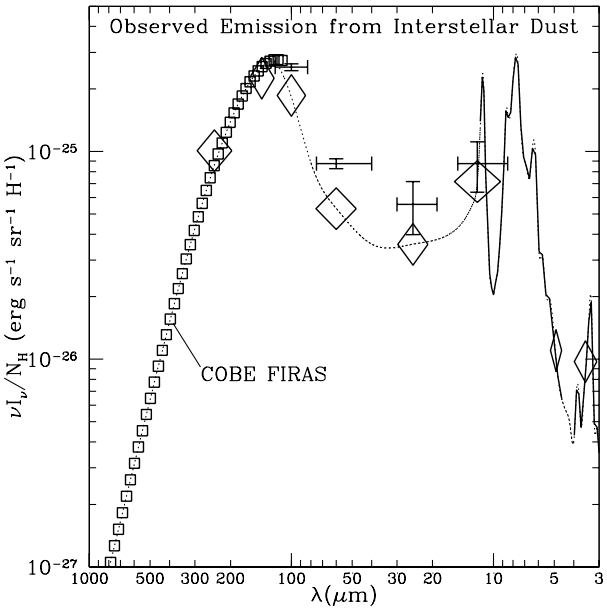

Figure 3. Infrared emission from interstellar dust grains from dust in diffuse clouds, per H nucleon. Crosses indicate data from the Infrared Astronomy Satellite (IRAS) at 100, 60, 25 and 12 μm. Squares indicate data from the FIRAS instrument on the Cosmic Background Explorer (COBE). Diamonds indicate data from the DIRBE instrument on COBE. The heavy full line at 12–5 μm and 4.6–3 μm is the spectrum measured by the Infrared Telescope in Space (IRTS).

(b) The presence in different parts of the interstellar medium of molecular hydrogen (H_2) with abundances far exceeding what could be produced by purely gas-phase processes. The required rate of H_2 catalysis on interstellar grain surfaces provides information on interstellar grain properties, including total surface area.

Extinction by interstellar dust grains

The 'extinction curves' shown in figure 1 represent the wavelength-dependent extinction A_λ at wavelength λ observed on different kinds of sightlines. Careful studies of the extinction on many lines of sight reveal that the extinction curves can be approximately described by a one-parameter family of extinction curves, and the curves shown in figure 1 are obtained from fitting functions originally developed by Cardelli *et al* (1989) and others. It is convenient to take $R_V \equiv A_V/(A_B - A_V)$ as the parameter, where $V = 550$ nm and $B = 440$ nm. Values of R_V as small as 2.75 and as large as 5.5 are observed in different regions.

Grains in diffuse regions tend to have $R_V \approx 3.1$, while larger values of R_V tend to be seen when studying the extinction by dust in dense clouds. Larger values of R_V—corresponding to 'greyer' extinction—are indicative of larger grains. The observed tendency for larger values of R_V to be found in denser regions strongly suggests that characteristic grain sizes are larger in these regions.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

It can be shown that the increased values of R_V cannot be explained simply by accretion of atoms and molecules from the gas phase—because of the very large amount of surface area contributed by the smaller grains, accretion from the gas phase would result in only a very small increase Δa in the radii of all grains, with minimal effect on the extinction at B and V. Instead, small grains must coagulate with larger grains to convert diffuse cloud dust to dense cloud dust.

Extinction features

The strongest spectroscopic feature in the extinction curve is a conspicuous 'bump' at 217.5 nm (see figure 1). This feature has approximately the wavelength and width expected for small (radius $a \leq 15$ nm) particles of graphite. While identification of the feature is still not certain, it appears highly likely that it is due to small carbonaceous particles with sp^2 carbon–carbon bonds as in graphite and polycyclic aromatic hydrocarbons. The strength of the 217.5 nm feature requires that ~15% of the solar abundance of carbon be present in small ($a \leq 15$ nm) particles.

Between 1.32 μm and 400 nm there are many weak diffuse extinction features, known as the 'diffuse interstellar bands', or DIBs. Approximately 300 such features have been identified, with full width at half-maximum (FWHM) ranging from ~0.05 nm up to ~4 nm. The strongest DIB is at 442.9 nm.

The first DIBs were recognized in 1934 by Merrill, yet they remain essentially unidentified to this date. They must be due to either 'impurities' within dust grains, or to small free-flying molecules (i.e. ultrasmall dust grains). A few of the weaker features have been identified recently as electronic transitions of C_7^-, and it seems likely that many other of the DIBs are also produced by small hydrocarbon molecules, either neutral or charged (either positively or negatively).

A broad extinction feature at 3.4 μm is attributed to the C–H stretching mode in aliphatic (chainlike) hydrocarbons. This feature is present in the diffuse interstellar medium.

There are strong infrared extinction features peaking at 9.7 μm and 18 μm which are almost certainly due to amorphous silicates with a composition approximating that of olivine ($Mg_xFe_{2-x}SiO_4$). In regions where the dust is hot (e.g. circumstellar dust, or the dust near the TRAPEZIUM in the ORION NEBULA), these features appear in emission. In some circumstellar dust shells and disks (e.g. the dusty disk around the Herbig Ae/Be star HD 100546), sharp features characteristic of crystalline silicates appear in emission, but these features have not been detected in either emission or absorption in the interstellar medium, indicating that the bulk of interstellar silicates are amorphous.

In dark clouds, a number of additional features appear in the infrared extinction, presumably due to growth of molecular ice mantles on the refractory dust grain cores. The strongest feature is at 3.08 μm and is due to amorphous H_2O ice. Additional features have been identified as frozen CH_3OH (3.53 μm), CO (4.67 μm), CH_4 (7.65 μm) and CO_2 (15.2 μm).

Alignment of dust grains

When initially unpolarized starlight passes through the dusty interstellar medium, it acquires both linear and circular polarization. The linear polarization is due to preferential attenuation of one linear polarization over the other, due to a population of non-spherical dust grains which are somehow aligned. The linear polarization peaks near $V = 550$ nm, with peak polarization $P \approx 0.03 A_V$. The circular polarization, generally quite small, is due to conversion of linear to circular polarization when the alignment direction of the dust grains undergoes a twist along the line of sight to the source.

Spinning dust grains have magnetic moments antiparallel to their angular velocities, and the angular momentum therefore precesses around the local galactic magnetic field. As a result, the observed direction of starlight linear polarization must be either parallel or perpendicular to the projection of the magnetic field on the sky. Theories of grain alignment lead us to expect the grain angular momentum to tend to align with the magnetic field, and the 'long' axis of the grains to tend to be perpendicular to the angular momentum. The long axis of the grain therefore tends to be perpendicular to the magnetic field, and as a result light becomes linearly polarized *parallel* to the projection of the magnetic field on the plane of the sky.

Our understanding of the physics of dust grain alignment is not yet complete, but it appears that the observed alignment in diffuse clouds is produced mainly by a combination of paramagnetic dissipation (originally proposed by Davis and Greenstein in 1951) and radiative torques on irregular dust grains due to anisotropic starlight. In some cases the alignment may result from drift of the dust grains through the gas cloud.

Scattering of light by dust grains

Reflection nebulae such as NGC2023 or the beautiful filamentary structures near the Pleiades show that dust grains scatter starlight. While most conspicuous when a bright star is located near the surface of a dense clouds, reflected starlight also manifests itself as the 'diffuse galactic light'—reflected starlight seen in all directions in the sky where there is dust. Measurements of the surface brightness of reflection nebulae, or of the diffuse galactic light, provide constraints on the scattering properties of interstellar dust grains—both the total 'albedo' $\omega = C_{\rm sca}/C_{\rm ext}$, and the angular dependence of the scattering, often characterized by $g \equiv \langle \cos\theta \rangle$, where θ is the scattering angle. At visible wavelengths, the albedo $\omega \approx 0.5$ and the grains are moderately forward-scattering, $g \approx 0.5$, consistent with current models for interstellar grains which reproduce the wavelength-dependent extinction as well as the infrared emission from dust.

Scattering by dust grains can also be observed at x-ray wavelengths. A grain is essentially transparent to

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$h\nu \geq 0.5$ keV x-ray photons. Since the refractive index of the grain material is very close to 1, the scattering can be calculated in the 'Rayleigh–Gans' approximation, and one finds that only small-angle scattering is expected. X-ray haloes around compact x-ray sources have been imaged by the EINSTEIN (HEAO-2) and ROSAT observatories; the observed x-ray haloes appear to be approximately consistent with the scattering expected for a grain model developed to account for the optical-UV extinction curve.

Dust grain luminescence

Observations of REFLECTION NEBULAE (e.g. NGC 7023) as well as the general interstellar diffuse clouds or 'cirrus' appear to show evidence of far-red continuum radiation in excess of what is expected from simple scattering of starlight by dust grains. The far-red emission peaks near ∼700 nm, and has a spectrum resembling the luminescence from hydrogenated amorphous carbon illuminated by $\lambda \leq$ 550 nm radiation. This suggests that some of the grain material may resemble hydrogenated amorphous carbon, although ultrasmall silicon grains have also been proposed as the source of the emission. Even if it is assumed that hydrogenated amorphous carbon is responsible for the observed emission, an accurate estimate of the quantity of material required is not possible, since luminescence efficiencies of hydrogenated amorphous carbon in the laboratory depend on the preparation of the sample.

Infrared emission from dust grains

Starlight is in part absorbed by dust grains, and the absorbed energy is re-radiated by dust grains in the infrared. The observed emission spectrum for interstellar dust is shown in figure 3. It consists of far-infrared emission peaking at $\lambda \approx 140\ \mu$m, plus substantial emission at shorter wavelengths.

The emission at $\lambda < 12\ \mu$m shows conspicuous emission features at 11.3, 8.6, 7.7, 6.2 and 3.3 μm; emission peaks at these same wavelengths have also been observed from reflection nebulae, planetary nebulae, HII regions, and circumstellar dust. The emission features have been identified as characteristic of polycyclic aromatic hydrocarbons (PAHs): C-H stretch (3.3 μm), C-C stretch (6.2 and 7.7 μm), in-plane C-H bend (8.6 μm) and out-of-plane C-H bend (11.3 μm). Variations in the relative strengths and precise wavelengths of these features from one object to another may be due to changes in the PAH mixture, including changes in the fraction which are positively or negatively charged.

The 'classical' grains with radii 0.01–0.3 μm radiate a spectrum characteristic of thermal emission at the (steady) temperature of the grain, ∼15–20 K for grains in the diffuse interstellar medium. This accounts for nearly all of the emission at $\lambda > 60\ \mu$m. For very small grains, however, absorption of a single starlight photon can appreciably change the grain temperature. For example, a single photon of energy $h\nu = 10$ eV can heat a 230 atom graphite grain to a peak temperature $T \approx 300$ K. At this temperature the grain can radiate effectively at wavelengths as short as $\lambda \approx 8\ \mu$m. The observed emission feature near 7.7 μm could therefore be due to thermal emission from grains with ∼100–300 atoms. The relatively large amount of power radiated at $\lambda < 10\ \mu$m requires that the grains with ≤300 atoms account for an appreciable fraction (≥15%) of the total absorption of starlight by interstellar grains.

Microwave emission from dust grains

Sensitive observations of the cosmic microwave background radiation have revealed 10–60 GHz emission from interstellar matter with intensities greatly exceeding what would be expected from an extrapolation of the thermal far-infrared emission to these lower frequencies. It appears likely that the observed 10–60 GHz emission is largely rotational electric dipole emission from very rapidly rotating ultrasmall grains, although a fraction of the radiation could be thermal emission from grains containing materials that are ferromagnetic (e.g. metallic Fe inclusions) or ferrimagnetic (e.g. magnetite Fe_3O_4).

Interstellar dust grains in the solar system

The solar system was formed out of interstellar gas and dust approximately 4.5 billion years ago. The formation of planetesimals and planets was accompanied in many cases by high temperatures and violent conditions, and most interstellar dust particles were destroyed. However, the class of meteorites known as carbonaceous chondrites (see METEORITES) contain small particles with unusual isotopic ratios (see ISOTOPIC ANOMALIES) which indicate that they did not form in the solar nebula, but rather must have been formed in a region with an anomalous composition (e.g. outflow from an evolved star) long before the formation of the solar system. Therefore these particles must have been part of the interstellar grain population prior to the formation of the solar nebula.

To date, five different types of presolar grains have been isolated and identified (see table 1). The evidence that the grains listed in table 1 were truly interstellar is compelling, but it is important to realize that they apparently do not include typical interstellar grains, for the simple reason that the procedures used to isolate interstellar grains in meteorites are designed to deliberately destroy silicate material (which comprises the bulk of the carbonaceous chondrite meteorite 'matrix'). These laboratory procedures are therefore *not* going to find interstellar silicate grains even if they are present.

Detectors aboard the Ulysses and Galileo probes measured impacts by interplanetary dust particles, but also observed impacts attributed to the flux of interstellar grains expected due to the 20 km s^{-1} motion of the Sun relative to the local interstellar medium. (see SOLAR WIND: ULYSSES, GALILEO MISSION) The detectors are sensitive only to collisions with the large-size end of the interstellar grain distribution, but the observed distribution of impact energies appears to be consistent with both the overall numbers and size distribution expected based on studies of interstellar extinction.

Table 1. Interstellar grains in meteorites.

Composition	Diameter (μm)	Abundance†
C (diamond)	0.002	5×10^{-4}
SiC‡	0.3–20	6×10^{-6}
C (graphite)‡	1–20	1×10^{-6}
Al_2O_3 (corundum)	0.5–3	3×10^{-8}
Si_3N_4	∼1	2×10^{-9}

† Mass fraction in 'primitive' carbonaceous chondrite meteorites.

‡ SiC and graphite grains sometimes contain very small TiC, ZrC, and MoC inclusions.

The lines of evidence listed above serve to strongly constrain theoretical models for the interstellar grain population. Unfortunately, interstellar grain researchers have thus far not been able to uniquely determine the grain model from the available observational constraints, so debates continue concerning the details.

Nevertheless, there is broad consensus on a number of properties of interstellar grains:

(a) The grain population must have a broad size distribution, with grain radii[2] covering the range 0.5–300 nm—a factor of at least 10^8 in grain mass.

(b) Most of the grain mass is in particles with radii $50 \leq a \leq 300$ nm.

(c) Most of the grain area is in particles with radii $a \leq 50$ nm.

(d) Approximately 50% of the grain mass in diffuse clouds is contributed by amorphous silicate material, accounting for the broad 9.7 μm and 18 μm silicate features. Most of the silicon, iron and magnesium abundance is in solid form.

(e) Approximately 50% of the grain mass in diffuse clouds is contributed by carbonaceous material. Approximately two-thirds of the total carbon abundance is in solid form.

(f) The 217.5 nm feature is probably due to some form of carbonaceous material, possibly graphitic.

Graphite-silicate grain model

It is not possible to invert the observations to obtain a unique grain model. Instead, one makes some assumptions concerning the grain composition and the form of the size distribution, and then attempts to adjust the model to achieve a good match to the observed interstellar extinction, infrared emission and other constraints such as observed gas phase abundances.

One grain model which has proven fairly successful in conforming to observations consists of a mixture of carbon grains and silicate grains. The carbon grain material is taken to have the optical constants of crystalline graphite. A good fit to the extinction can be obtained if both graphite and silicate grains have size distributions which are approximately a power-law, $dn/da \propto a^{-3.5}$, truncated at $a_{\rm min} \approx 5$ nm and $a_{\rm max} \approx 250$ nm The 217.5 nm feature is then reproduced by the $a \leq 15$ nm graphite grains. This grain model—the combination of graphite and silicate grains, and the $dn/da \propto a^{-3.5}$ power law—was first put forward in 1977 by Mathis, Rumpl and Nordsieck, and is often referred to as the 'MRN' model. The MRN model achieves a good fit to the $R_V = 3.1$ extinction curve for diffuse clouds with essentially all of the Mg, Si and Fe in the silicate grains, and approximately two thirds of the C in the graphite grains, in reasonable agreement with observed depletions. The grains are heated to temperatures ∼18 K by starlight, and the resulting thermal emission is approximately consistent with the observed far-infrared emission at $\lambda > 60\mu$m.

[2] The particles are of course not spherical. By grain 'radius' we refer to the radius of a sphere of equal volume.

Ultra-small dust grains

Unfortunately, the original graphite-silicate grain model described above fails to reproduce the $\lambda < 50$ μm infrared emission shown in figure 3. The model lacks the ultrasmall grain component required to explain the observed $3 \leq \lambda \leq 50$ μm infrared emission from interstellar dust. The simplest modification is to allow the carbon grain distribution to extend down to very small sizes, with the smallest grains assumed to have infrared optical properties suitable to explain the emission features at 3.3, 6.2, 7.6, 8.6 and 11.2 μm when heated to the appropriate temperatures by absorption of single starlight photons. In order to have sufficient numbers of ultrasmall grains, while still reproducing the extinction curve, the size distribution of at least the carbonaceous grains can no longer be approximated by a single power law.

Other grain models

Other grain models, with different grain geometries and/or compositions, have been proposed to account for the observed interstellar extinction and infrared emission:

(a) Mathis and Whiffen proposed a grain model wherein the larger grains are porous aggregates of small graphite and silicate particles.

(b) Some authors have favored metal oxides (MgO, SiO, FeO), either in addition to or in place of silicates.

(c) Some models assume the silicate grains in diffuse clouds to be coated with a carbonaceous 'mantle' material, which might be hydrogenated amorphous carbon.

(d) Metallic Fe and FeS incorporate significant fractions of the Fe in some grain models.

(e) Small particles of crystalline silicon, with hydrogenated or oxidized surfaces, have been proposed as an explanation for the observed luminescence near ∼700 nm.

Grain models generally tend to have the bulk of the Fe, Mg, Si in dust, approximately two-thirds of the C, and about 20% of the O, resulting in dust-to-gas mass ratios of ∼0.007.

Dynamics of interstellar grains

Interstellar grains are acted on by forces due to a number of distinct physical processes, including:

(a) Gas drag forces when the grain velocity differs from that of the gas. In addition to direct collisions with atoms and ions, there is also a 'plasma drag' force on charged grains due to momentum transfer with ions which do not actually collide with the grain. For subsonic motion, the plasma drag force is typically a factor of ∼20–30 larger than the drag due to direct collisions with ions.

(b) Electromagnetic forces on charged grains. Since there is usually a 'plasma' reference frame in which the electric field is very small (interstellar plasma being a very good conductor), the electromagnetic force can be attributed to the Lorentz force $\boldsymbol{F} = Q(\boldsymbol{v}/c) \times \boldsymbol{B}$, where Q is the grain charge, $\boldsymbol{B}$ is the magnetic field and $\boldsymbol{v}$ is the grain velocity relative to the plasma.

(c) Scattering and absorption of photons ('radiation pressure') when the grain is illuminated by an anisotropic radiation field.

(d) Poynting–Robertson drag, as when a grain is moving perpendicular to a directional radiation field. While not normally important in the interstellar medium, Poynting–Robertson drag can be very important for dust grains orbiting stars (see INTERPLANETARY DUST).

(e) Recoil forces when photoelectrons or photodesorbed molecules are emitted anistropically from a grain which is illuminated by an anisotropic ultraviolet radiation field.

(f) Gravitational force. In clouds supported by gas pressure, dust grains will tend to 'sediment' toward the minimum of the gravitational potential.

Because the gas and grains are subject to different forces, the dust grains generally have a drift velocity relative to the gas. In typical diffuse clouds, anisotropic starlight can result in drift velocities of order ~ 0.1 km s^{-1}. In regions with strongly anisotropic ultraviolet radiation fields (such as photodissociation regions) the drift velocities can be larger.

The rotational dynamics of interstellar grains are also of great interest, in connection with both the problem of grain alignment (which requires alignment of the grain angular momentum vector with the local magnetic field) and with electric dipole radiation which will be radiated by very rapidly rotating ultrasmall grains. The grain angular momentum is affected by: collisions with gas atoms and molecules; recoil associated with photoelectric emission; recoil associated with H_2 formation on the grain surface; absorption and scattering of starlight by an asymmetric grain; thermal infrared emission; the interstellar magnetic field acting on the magnetic dipole moment resulting from the Barnett effect in a spinning grain; and the interstellar magnetic field acting on the magnetization induced in the spinning grain by the interstellar magnetic field (the 'Davis–Greenstein' torque associated with paramagnetic dissipation).

Because the interstellar medium is far from thermodynamic equilibrium, some of these torques can act systematically.

Grains can be driven to rotational kinetic energies much larger than $kT_{\rm gas}$ (where $T_{\rm gas}$ is the gas temperature) by collisions with gas atoms and molecules (because the grain and gas temperatures differ), by photoelectric emission or by absorption and scattering of starlight (because the starlight radiation field is not in thermodynamic equilibrium with the grain temperature), and by H_2 formation (because the H_2 abundance and gas and grain temperatures are not in thermodynamic equilibrium).

Gradual alignment of the grain angular momentum with the magnetic field can be produced by paramagnetic dissipation (because the grain rotational kinetic energy is not in thermodynamic equilibrium with the 'vibrational' temperature of the grain).

Effects of interstellar grains

Photoelectric heating

Perhaps the most important effect of interstellar dust grains is their role in heating the gas via photoelectric emission. When a dust grain absorbs an ultraviolet photon of energy $h\nu$, there is a probability $Y(h\nu)$—often referred to as the 'yield'—that a photoelectron will escape from the grain surface and thermalize with the local gas. When this happens, the kinetic energy of the emitted electron (at 'infinity', since the grain it is escaping from may be charged) acts to heat the interstellar medium. On average, grains must capture electrons as rapidly as they are ejected, and the net heating rate then is equal to the difference between the mean energy of the emitted electrons and the captured electrons. Since photoelectric yields Y may be of the order of ∼10%, and since the kinetic energy of the electron at infinity may be of the order of ∼1 eV (if the grain is not highly positively charged) the photoelectric heating mechanism, at best, converts a few per cent of the absorbed ultraviolet starlight energy into heating of the gas. While this few per cent conversion efficiency may seem small, the availability of energy in starlight is so great that photoelectric heating is generally the dominant heating mechanism for diffuse interstellar gas.

Radiative forces on dust grains

In astrophysics, anisotropic radiation fields are the rule rather than the exception, and these anisotropic radiation fields can have dynamical consequences for dust and gas. Circumstellar grains are of course subject to extremely anisotropic radiation from the star. At a typical point in the interstellar medium, the non-uniform distribution of stars in the galaxy, together with patchy obscuration by interstellar dust, results in starlight with appreciable anisotropy. The dipole component of the starlight anisotropy may be typically ∼10%.

When the radiation field is anisotropic, scattering and absorption by the grain produces a net force on the grain, commonly referred to as the 'radiation pressure' force. If the grain is coupled collisionally to the gas by gas drag and perhaps magnetic fields, then the force exerted on the grains is transmitted to the gas. These radiation pressure forces can dominate the dynamics of gas in certain regions, such as dust-forming winds from cool stars.

H_2 formation on grains

Interstellar chemistry largely starts with the catalysis of H_2 on interstellar grain surfaces (see INTERSTELLAR CHEMISTRY). The inferred production rate of H_2 in the interstellar medium requires that an appreciable fraction of the H atoms arriving at interstellar grains surfaces must leave the grains as part of H_2 molecules. While the details of the kinetics remain uncertain, the overall picture is broadly as follows: when an H atom in a diffuse cloud arrives at a grain surface it has a high probability of sticking. The H atom then explores some fraction of the grain surface by either thermal diffusion or quantum tunnelling, until it either finds another H atom with which it can recombine to form H_2, or it arrives at a location on the grain surface where the binding by either van der Waals forces ('physisorption') or formation of a chemical bond ('chemisorption') is strong enough that it becomes trapped. If such trapping occurs, then the surface coverage of trapped H atoms builds up until newly arrived H atoms have an appreciable probability of reacting with a previously trapped H atom rather than becoming trapped themselves, or the adsorbed H atoms are removed by some other process (e.g. photodesorption or thermal desorption).

Coupling magnetic fields to neutral gas

Dynamically important magnetic fields are commonly present in interstellar gas (see INTERSTELLAR MAGNETIC FIELDS). In a dense molecular gas with very low fractional ionization, a large fraction of the 'free' charge resides on positively and negatively charged dust grains. Under these conditions—which prevail in high-density regions in molecular clouds, and presumably in protostellar disks—dust grains dominate the coupling of magnetic fields to the gas, since the neutral gas atoms and molecules themselves are not directly coupled to the magnetic field. The charged dust grains are coupled both to the magnetic field (by Lorentz forces) and to the neutral gas (by collisional drag). As a result, the grains will drift with a velocity which is intermediate between the velocity of the neutral gas and the velocity with which the magnetic field lines (and plasma) 'slip' through the neutral gas. Thus the dust grains determine the rate of 'ambipolar diffusion' of magnetic field lines in dense molecular regions.

Charged dust grains play a similar role in the dynamics of magnetohydrodynamic shock waves in gas of low fractional ionization but dynamically significant magnetic fields.

Formation and destruction of interstellar grains

While interstellar grains are observed to be ubiquitous, it is not obvious that this should be so. In the violent interstellar medium (see INTERSTELLAR MATTER, SUPERNOVA REMNANTS), grains can be destroyed when the gas which they are in is overtaken by a shock wave with shock speed $v_s \geq 200$ km s^{-1}, as is expected in supernova blastwaves. Estimates of the rate of occurrence of supernovae, together with models for the resulting blastwaves, lead one to estimate that the mass in interstellar grains will be returned to the gas phase on a timescale of $\sim 5 \times 10^8$ yr, short compared with the age of the Galaxy and the interstellar medium. We know that grains are injected into the interstellar medium in outflows from cool red giants and supergiants, and even in supernova ejecta, but if there were no conversion of gaseous atoms back to solid form in the interstellar medium, we would expect very little grain material to be present at any time. In particular, even for elements like Fe we would expect most of the atoms to be in the gas phase. The fact that this is not so—that most of the interstellar Fe is in fact missing from the gas phase—requires that there be efficient recondensation of Fe, Si, Ca and other elements back into solid form *in the interstellar medium*. The 'mineralogy' of interstellar grains must therefore largely reflect the surface chemistry which will occur on the surfaces of interstellar grains.

Interstellar Magnetic Fields

The interstellar medium is permeated by magnetic fields that have important astrophysical consequences. This article describes how interstellar magnetic fields are detected, measured and mapped, the results of such observations and the role played by interstellar magnetic fields in the physics of the interstellar medium.

The intensity of SYNCHROTRON RADIATION may be used to infer the strength of the magnetic field in the plane of the sky, $B_\perp$. Synchrotron radiation is polarized perpendicular to $B_\perp$, so POLARIZATION observations map the geometry of interstellar magnetic fields. Also, the percentage polarization is a measure of the ratio B_u/B_t of uniform to total fields. Dust grains are aligned by magnetic fields, and the linear polarization of background starlight and thermal dust emission traces the geometry of magnetic fields. A new technique that also traces $B_\perp$ is mapping of linearly polarized spectral-line emission.

Faraday rotation of the position angle of linearly polarized radiation may be used to measure the strength of magnetic fields parallel to the line of sight, $B_\parallel$, if the density of interstellar electrons is known. By observing the dispersion measures of pulsars, $B_\parallel$ weighted by the electron density may be determined. Finally, detection of Zeeman splitting of spectral lines gives $B_\parallel$.

Although the various probes sample different phases and regions of the interstellar medium, a fairly consistent picture has emerged. The Galactic interstellar magnetic field has a spiral pattern, with reversals in field direction in interarm regions. Near the Sun $B_t \approx 5$–$10\ \mu$G, with a ratio of uniform to random components $B_u/B_r \sim 0.3$–0.7. The field strength increases inward in the Galaxy, with milligauss fields in the Galactic center. The Galactic magnetic field is probably maintained by a Galactic dynamo, although the details are very unclear.

The interstellar gas, cosmic ray gas and magnetic fields are an unstable dynamic system, with blast waves from SUPERNOVAE inflating the system and extending lobes of magnetic field, hot gas and COSMIC RAYS outward from the Galactic plane to form the Galactic halo.

Observations of the position angles of dust polarization generally show little small-scale variation in interstellar clouds; analysis suggests that uniform and tangled field components may be roughly comparable in strength. Magnetic field strengths increase little with gas density up to $n(H_2) \sim 10^3$ cm^{-3}, with $B \approx 10$–$20\ \mu$G in diffuse interstellar clouds and extended dark clouds; at higher densities the data are consistent with the theoretical prediction $B \propto n^{1/2}$. In some molecular cores there is evidence for the 'hourglass' pinch that would be produced by cloud contraction with the magnetic field frozen into the matter. Strengths of the uniform component of magnetic fields in molecular clouds are only slightly less than the critical values needed for support against gravitational collapse. Hence, magnetic fields play a crucial role in the STAR FORMATION process.

Observational techniques

All methods of observing magnetic fields in the interstellar medium are sensitive only either to the component of $\boldsymbol{B}$ parallel to the line of sight, $B_\parallel$, or to the component in the plane of the sky, $B_\perp$. Direct tracers involve the detection of polarized radiation emitted by or passing through the interstellar medium.

Polarization

The polarization of electromagnetic radiation may be conveniently described by the Stokes parameters I, Q, U and V, where I describes the total intensity, Q and U describe the linear polarization and V describes the circular polarization of radiation. The electric vector of an electromagnetic wave propagating along the z-axis may be resolved into two orthogonal components

$$E_x(t) = E_1 \cos(2\pi\nu t)$$

$$E_y(t) = E_2 \cos(2\pi\nu t + \phi).$$

Then

$$I = E_1^2 + E_2^2$$

$$Q = E_1^2 - E_2^2$$

$$U = 2E_1E_2 \cos(\phi)$$

$$V = 2E_1E_2 \sin(\phi)$$

and the total polarized intensity is

$$I_p = (Q^2 + U^2 + V^2)^{1/2}.$$

What are often stated for observations of linear polarization are the fractional polarization I_p/I and the position angle ψ of the major axis of the polarization ellipse,

$$\psi = \frac{1}{2} \arctan\left(\frac{U}{Q}\right).$$

If radiation is observed with a detector sensitive to linear polarization, the maximum signal will be detected when the detector is oriented at the position angle ψ. If a detector sensitive to circular polarization is used to measure the intensities I_R and I_L of the right and left circularly polarized components, Stokes V may be inferred directly from the difference. Unfortunately, there is not a standard used consistently by astronomers for the sense of circular polarization, so care must be exercised.

Tracers of $B_\perp$

Synchrotron radiation

An electron moving with velocity $\boldsymbol{v}$ at an angle θ to a magnetic field $\boldsymbol{B}$ will move in a helical path around the field lines owing to the Lorentz force $\boldsymbol{v} \times \boldsymbol{B}$ and will therefore emit electromagnetic radiation as a result of this acceleration. An ensemble of electrons is generally treated by assuming that the distribution function of the energies of the electrons is a power law with index p:

$$N(E)\,\mathrm{d}E = N_0 E^{-p}\,\mathrm{d}E.$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

For an assumed uniform magnetic field in a region of extent L along the line of sight, the intensity of radiation that would be emitted is given by

$$I(\nu) = \frac{\sqrt{3}e^3 L}{8\pi mc^2}\left(\frac{3e}{4\pi m^3 c^5}\right)^n N_0 B_\perp^{n+1}\nu^{-n}a(n)$$

where $n = (p-1)/2$ and $a(n)$ is a slowly varying function of order unity. For a uniform magnetic field the fractional linear polarization is

$$\frac{I_p}{I} = \frac{n+1}{n+5/3}.$$

Hence, by measuring the position angle of the linearly polarized synchrotron radiation emitted by highly relativistic electrons ($\gamma \gg 10^3$), the direction of the magnetic field in the plane of the sky may be mapped. An estimate of the ratio of strengths of the random (B_r) and uniform (B_u) components of the magnetic field may be obtained from the degree of polarization, since for a completely random field the synchrotron radiation will be unpolarized.

By making various assumptions, the most important being equilibrium between the energy densities of the relativistic electrons and of the magnetic field, an estimate of the strength of the magnetic field may be obtained from the flux density S_ν of the synchrotron emission:

$$B_\mathrm{eq} = f(n)\frac{D^2}{V}(S_\nu \nu^n)^{2/7}$$

where D is the distance to the emitting gas, V is its volume and $f(n)$ is a function of n.

These techniques are most useful for mapping the large-scale morphologies of interstellar magnetic fields in external galaxies and in the Milky Way.

Dust polarization

Linear polarization at optical, infrared or millimeter wavelengths arises from elongated grains with their short axes aligned with the magnetic field. The Davis–Greenstein mechanism assumes that INTERSTELLAR GRAINS are aligned via paramagnetic relaxation, which damps the components of a grain's angular momentum perpendicular to $\boldsymbol{B}$, gradually aligning the spin axis with the magnetic field direction. Although the original Davis–Greenstein theory considered only thermal spins, much weaker magnetic fields can align grains because of superthermal spin energies produced by ejection of H_2 molecules from their formation sites on grains. Internal damping due to Barnett relaxation normally causes the grain to spin about its axis of greatest moment of inertia, so the long axis of the grain is oriented perpendicular to the field.

However, there are other alignment mechanisms. One which may dominate paramagnetic relaxation in protostellar jet or wind regions is Gold alignment, in which gas streaming past the grains excites their angular momenta perpendicular to the flow direction, causing the grains to tend to rotate with their long axes parallel to the flow. Unless there is reason to believe that some other process dominates, Davis–Greenstein alignment is assumed.

Grain properties and the grain alignment mechanism are not understood in sufficient detail for field strengths to be reliably inferred, but observations of linear polarization trace the position angle of the component of $\boldsymbol{B}$ in the plane of the sky.

Starlight passing through the interstellar medium will be linearly polarized owing to extinction by aligned interstellar grains along the line of sight, so long as the magnetic field is not completely random. Because Davis–Greenstein alignment produces the maximum extinction cross-section perpendicular to the magnetic field, extinction will be greater perpendicular to field than parallel to it. Hence, the position angle of the polarization ellipse of background starlight will be parallel to the magnetic field direction. On the other hand, when emission from dust grains is observed, the position angle of maximum emission will be perpendicular to the magnetic field. Thermal emission from linearly polarized dust grains at far-infrared and millimeter wavelengths may be used to map magnetic field morphologies.

Spectral-line linear polarization

Linear polarization may also arise in radio frequency spectral lines formed in the interstellar medium. This Goldreich–Kylafis effect may be used to probe magnetic field morphologies in molecular clouds. For a molecule with (say) levels with total angular momenta $F = 1$ and $F = 0$, in the presence of a magnetic field the degeneracy of magnetic sublevels will be removed and the level with $F = 1$ will be split into three sublevels. The three transitions will be polarized as usual for this situation, but so long as the three sublevels of the $F = 1$ state are populated equally, the net polarization is zero. If the line optical depth to the source is anisotropic, the radiation field will be anisotropic and the radiative rates between level $F = 0$ and the three sublevels of $F = 1$ will be unequal. Thus, unequal populations of the three sublevels can be sustained, and net linear polarization will result. Since astrophysical sources are always anisotropic at some level, linear polarization of line emission is expected. The degree of polarization depends on the degree of anisotropy, the optical depth of the spectral line, the angles between the line of sight, the magnetic field, and the axis of symmetry of the velocity field, and the ratio of the collisional excitation rate to the radiative rate. The direction of the polarization can be either parallel or perpendicular to the magnetic field; therefore, care must be taken in inferring the direction of $\boldsymbol{B}$.

Tracers of $B_\parallel$

Faraday rotation

A linearly polarized electromagnetic wave may be decomposed into two oppositely circularly polarized

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

waves. These two waves propagate through an interstellar medium that contains ions and magnetic fields with different phase velocities. The result is that the position angle of the linear polarization will rotate. This Faraday rotation produced by propagation through a path length L is given by

$$\Delta\psi = \frac{e^3}{2\pi m^2 c^2 \nu^2} \int_0^L B_\parallel(z) n_e(z)\, \mathrm{d}z.$$

Hence, observations of Faraday rotation of linearly polarized radiation (usually synchrotron radiation) may be used to infer the strength of the line-of-sight component of $\boldsymbol{B}$ if information about the electron density is known or assumed. Faraday rotation is generally quoted as a rotation measure,

$$RM = -\int_0^L B_\parallel n_e\, \mathrm{d}z.$$

Note the convention that a negative RM means $\boldsymbol{B}$ is pointed away from the observer, $B > 0$.

In the special case of observations of PULSARS, information about the electron density may be obtained from the dispersion with radio frequency in the arrival time of radio pulses. The dispersion measure is given by

$$DM = \int_0^L n_e\, \mathrm{d}z.$$

Then the mean line-of-sight component of $\boldsymbol{B}$ is

$$\overline{B}_\parallel = \frac{\mathrm{RM}}{\mathrm{DM}}.$$

This $B_\parallel$ is a vector average along the line of sight and may be much smaller than the localized fields if there are reversals in field direction.

Zeeman splitting

If a spectral line forming region is permeated by a field $\boldsymbol{B}$, the radiation is split by the normal ZEEMAN EFFECT into three separate frequencies, $\nu_{\sigma-} = \nu_0 - \nu_Z$, $\nu_\pi = \nu_0$ and $\nu_{\sigma+} = \nu_0 + \nu_Z$, where ν_0 is the line frequency, $\nu_Z = BZ$ and Z is the Zeeman sensitivity in Hz $\mu\mathrm{G}^{-1}$. For a magnetic field in the plane of the sky, the three Zeeman components are linearly polarized with the π component parallel to and the σ components perpendicular to the magnetic field direction. For a magnetic field along the line of sight, $I_\pi = 0$ and the I_σ are oppositely circularly polarized. If the magnetic field is parallel (antiparallel) to the direction of propagation of the radiation, $I_{\sigma+}$ is right (left) circularly polarized. In the general case of arbitrary angle between the line of sight and the magnetic field, all three Zeeman components will be elliptically polarized.

If B is sufficiently large, then $\nu_Z \sim \Delta\nu$ where $\Delta\nu$ is the line width. Then the Zeeman components may appear separated, and the full magnetic field strength can be derived directly from the measured ν_Z. Generally $\nu_Z \ll \Delta\nu$, and it is not possible to infer complete information about B from Zeeman observations. Although the Stokes parameters V, Q and U for the Zeeman components provide in principle full information about magnetic field strength and direction, in practice full information on $\boldsymbol{B}$ cannot be obtained owing to the extreme weakness of Q and U (typically about an order of magnitude weaker than V). The Stokes V spectra reveal the sign (i.e. direction) and magnitude of the line-of-sight component $B_\parallel$. That is, $V = (\mathrm{d}I/\mathrm{d}\nu)\nu_Z \cos(\theta)$. By fitting the frequency derivative of the Stokes parameter I spectrum $\mathrm{d}I/\mathrm{d}\nu$ to the observed V spectrum, $B_\parallel = \nu_Z \cos(\theta)/Z$ may be inferred.

For a large number of clouds whose magnetic fields are randomly oriented with respect to the observed line of sight, it is possible to infer statistically the mean correction to go from $B_\parallel$ to $|\boldsymbol{B}|$. That is,

$$\overline{B}_\parallel = \frac{\int_0^{\pi/2} |\boldsymbol{B}| \cos\theta \sin\theta\, \mathrm{d}\theta}{\int_0^{\pi/2} \sin\theta\, \mathrm{d}\theta} = \frac{1}{2}|\boldsymbol{B}|.$$

In general, only those species with an unpaired outer electron will have a magnetic moment that scales with the Bohr magneton, $M_\mathrm{B} = eh/4\pi mc = 1.4$ Hz $\mu\mathrm{G}^{-1}$. For the 1420 MHz line of H I, $Z = M_\mathrm{B}$. Molecular lines that are sensitive to the Zeeman effect have $Z \approx M_\mathrm{B}$; for example, $Z = 0.98$ Hz $\mu\mathrm{G}^{-1}$ for the 1667 MHz line of OH. Otherwise, the Zeeman effect will scale with the nuclear magneton, 1840 times smaller than M_B. Unfortunately, most molecules do not have large Zeeman splitting factors Z, so the possibilities for Zeeman observations are limited. Lines for which the Zeeman effect has been detected that have been used for measurements of interstellar magnetic fields are the 21 cm line of H I, 18 cm and 2 cm lines of OH, the 1.3 cm H_2O maser line and the 3 mm lines of CN. Other possible Zeeman molecules that might become useful probes of interstellar magnetic fields include CH, CCS and SO.

Magnetic field of the Milky Way

Polarization of starlight produced by interstellar magnetic fields was discovered accidentally about 50 yr ago during a search for polarization produced in STELLAR ATMOSPHERES. It was clear that the interstellar medium was responsible for the observed polarization because its amount correlated with interstellar extinction. Dust grains aligned by magnetic fields produce the polarization. Polarization of background stars provides a useful technique for measuring the morphology of interstellar magnetic fields near the Sun. Optical and near-infrared polarization data now exist for thousands of stars.

Figure 1 shows a plot of starlight polarizations for nearly 10 000 stars. Each line represents the polarization measurement for a star; the length is proportional to the fractional polarization and the orientation is in the direction of maximum polarization, which is parallel to the magnetic field. These data show several important characteristics of the local interstellar magnetic field. First, for Galactic latitudes b within about 10° of the Galactic

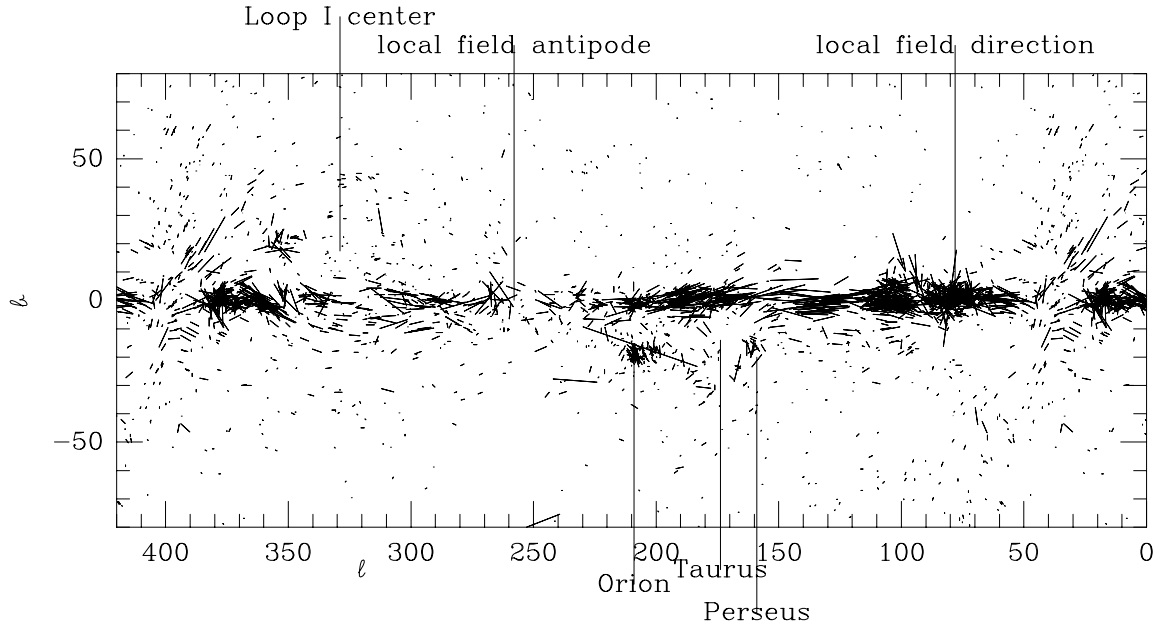

Figure 1. Starlight polarization defining the direction of the Galactic magnetic field near the Sun. The direction of the local spiral arm field, the Loop I interstellar bubble and star formation regions in Taurus, Perseus, Ophiuchus and Orion are marked.

plane, the magnetic field is generally parallel to the plane of the Galaxy. Looking directly along the local spiral arm, toward Galactic longitudes of $\ell \sim 80^\circ$ and $\ell \sim 260^\circ$, the polarization directions show convergence down the spiral arm. The polarization data suggest that the interstellar magnetic field is not heavily tangled on large spatial scales and lies in spiral arms. In principle it is possible to derive the ratio B_u/B_r from an analysis of the uniformity of the optical polarization data. The results are somewhat dependent on models that must be adopted for the analysis, but are reasonably self-consistent: $B_u/B_r \approx$ 0.7–1.0.

At positions more than $\sim 10^\circ$ off the Galactic plane there is considerable small-scale structure. Positions in Taurus, Perseus, Ophiuchus and Orion correspond to massive molecular clouds undergoing active star formation; the magnetic field lines are obviously perturbed from the regular, large-scale pattern. Finally, at high Galactic latitude several local interstellar bubbles each produced by multiple supernovae may be seen. The most prominent is Loop I, whose walls are outlined by a loop of magnetic field lines with a radius of $\sim 60^\circ$.

Synchrotron emission may be used to infer the total (uniform and random) strength B_t of the Galactic magnetic field. Maps of the Galaxy in radio synchrotron emission show spiral arms, implying that B is stronger in arm than in interarm regions. Derivation of the field strengths involves various assumptions and careful analysis—the best recent results are the following. Near the solar circle ($R = 8.5$ kpc is used here), $B_t \approx 6\ \mu$G in spiral arms and $B_t \approx 4\ \mu$G when averaged azimuthally, which includes arm and interarm regions. By scaling this azimuthal value by the observed increase in synchrotron emission with decreasing Galactic radius, at $R = 4.0$ kpc one finds $B_t \approx 8\ \mu$G. Near the solar circle the ratio of the uniform to the random magnetic field strength $B_u/B_r \approx 0.5$ from the ratio of the observed to the maximum possible synchrotron polarization.

Synchrotron emission decreases with height above the Galactic plane. When modeled as a thin and thick disk with equal emission at the Galactic plane, the scale heights are about 0.2 and 1.8 kpc at the Sun. Also, the scale height increases with Galactic radius. Because synchrotron emission depends on $B_\perp^{n+1}$, the scale height of B is significantly larger than that of the synchrotron emission.

Faraday rotation of the linearly polarized radiation from pulsars and extragalactic RADIO SOURCES provides information about the strength of the interstellar magnetic field along the line of sight. Pulsar data give the mean field $\overline{B}_\parallel$ directly from the ratio RM/DM. However, $\overline{B}_\parallel$ is a weighted mean, weighted by the electron density; this method therefore samples mainly the warm ionized component of the interstellar medium, which is believed to occupy a small fraction of the volume of interstellar space.

The pulsar data show clear evidence for reversals in the magnetic field direction at Galactocentric radii corresponding roughly to interarm regions in the Galaxy. The field in the local spiral arm points in the direction of Galactic rotation, with reversals at $R \approx 5.5$, 8.1 and 9.4 kpc. $\overline{B}_\parallel \approx 1.4\ \mu$G near the Sun, rising to $\sim 3.5\ \mu$G in the Sagittarius arm and $\sim 6.5\ \mu$G inside the second reversal radius (5.5 kpc). Note that these values are for the uniform component, B_u, only. Statistical analysis of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

deviations of $\overline{B}_\parallel$ from a uniform field or from comparisons of $\overline{B}_\parallel$ values from pulsars close together in the sky yields estimates of the strength of the random component of the magnetic field; the result is $B_r \approx 5\ \mu$G. Therefore, $B_u/B_r \approx 0.3$.

The H I Zeeman effect may also be used to measure $B_\parallel$ in diffuse interstellar gas. Extensive observations of truly randomly selected regions do not exist. One study of a large region in which RMs are consistently large and negative yielded many upper limits $B_\parallel \approx 7\ \mu$G, with detections at lower values when greater sensitivity was achieved. One position with $B_\parallel \approx 12\ \mu$G came from an H I filament probably produced by an interstellar shock which compressed both the gas and the field. Observations of the H I Zeeman effect toward well-known interstellar bubbles (Loop I, Loop II, the Eridanus bubble) yield $B_\parallel \sim 5$–$10\ \mu$G. The magnetic field has been enhanced by compression in the walls of the bubbles. When the H I Zeeman effect is detected in diffuse clouds, the observations yield typical values $B_\parallel \sim 5$–$20\ \mu$G (although there are many upper limits $B_\parallel < 5\ \mu$G), with clouds of densities up to $n(\mathrm{H\,I}) \sim$ several hundred being sampled. Hence, there is very little increase in B with gas density for $n < 10^3$ cm^{-3}.

Differences in results derived from pulsar, optical polarization, H I Zeeman and synchrotron emission studies may be attributed to the different phases of the interstellar medium being sampled. Pulsars sample the warm ionized medium, optical polarization and H I Zeeman sample primarily the neutral medium, and synchrotron emission samples the entire volume.

The central region of the MILKY WAY GALAXY has very strong magnetic fields, with strengths of several milligauss. Evidence for strong fields comes from large-scale, linear filaments of radio emission, highly polarized radio continuum emission, polarized infrared emission, Zeeman measurements of H I and OH absorption, and anisotropic scattering of radio emission from small sources. Models of the Galactic center have a circumnuclear disk threaded by a poloidal field, with the rotation of the disk producing an azimuthal component.

Magnetic fields in galaxies

A problem in studying the interstellar magnetic field in the Milky Way galaxy is that we are inside it, which allows detailed studies of the local interstellar medium but makes global study difficult. Observations of synchrotron emission from external galaxies provide a picture of the large-scale interstellar magnetic fields in SPIRAL GALAXIES. Maps of the linear polarization of synchrotron radiation are maps of the ordered component of $B_\perp$. In general magnetic field lines show a strong spiral structure. Sometimes the polarization maps define spiral structure even more clearly than tracers of material spiral arms, although often the magnetic spiral arms are found offset from the material arms. A possible reason for this is that magnetic fields in the densest parts of spiral arms are somewhat tangled or random owing to star formation or supernova activities, reducing the fractional polarization. Downstream from the spiral density-wave shock, gas will be accelerated away from the shock in streaming motions, which will act to untangle magnetic field lines and increase the polarization. Hence, the direction of $B_\perp$ in spiral galaxies may be the best technique for study of these large-scale streaming motions in spiral galaxies.

Although the magnetic fields in spiral galaxies are symmetric, there does not seem to be a single symmetry mode. In some an axisymmetric spiral arm pattern dominates with the magnetic field direction everywhere directed inwards along the spiral pattern. Others have a bisymmetric mode, with reversals in the direction of magnetic fields from one arm to the next, as seen in the Milky Way Galaxy. (It should be noted that only a few galaxies are classifiable in this way.) The strong spiral magnetic patterns are probably best explained by dynamo action in spiral galaxies. A typical value for the total magnetic field strength in galaxies is $B_t \approx 10\ \mu$G, with large uncertainties.

Magnetic fields and star formation

Magnetic fields may play two crucial roles in the star formation process—they can provide support against gravitational collapse of dense interstellar clouds and they can solve the problem of how angular momentum is transported away from collapsing protostellar cores.

Observations of the field geometry provide significant empirical input to and tests of theories. Background starlight polarization observations show that large-scale fields in clouds are smooth, with little change in the vicinity of clumps or cores. For extinction $A_V > 2$ magnitudes, near-infrared observations make it possible to probe up to $A_V \sim 40$ magnitudes. The field morphologies in dense clouds and cores observed in this way seem to be the same as in the envelope regions. However, the percentage polarization does not seem to increase much beyond about $A_V \approx 1.3$ magnitudes, which suggests that the grains in dense clouds do not produce polarization and hence cannot be used to map magnetic field morphologies at large extinctions.

Far-infrared and millimeter wavelength observations of thermal dust emission have proven to be the best technique for probing magnetic field morphology in dense interstellar clouds. Since the emission is generally optically thin, this technique samples material throughout dense molecular gas. However, sensitivity limits this technique to $A_V > 20$ magnitudes. The maps show that the polarization directions in dense molecular clouds are generally fairly uniform, at least on large spatial scales. Figure 2 shows far infrared polarization observations of $B_\perp$ in Orion Molecular Cloud 1 (OMC1). The typical percentage polarization is ∼2%, although values up to ∼10% are observed. Analysis of the OMC1 data suggests that there is an 'hourglass pinch' to the field lines, as expected toward dense cores on theoretical grounds. At the higher angular resolution available with mm-wave arrays, more structure is seen. In particular, near the dense central core there is a change in position angle of almost

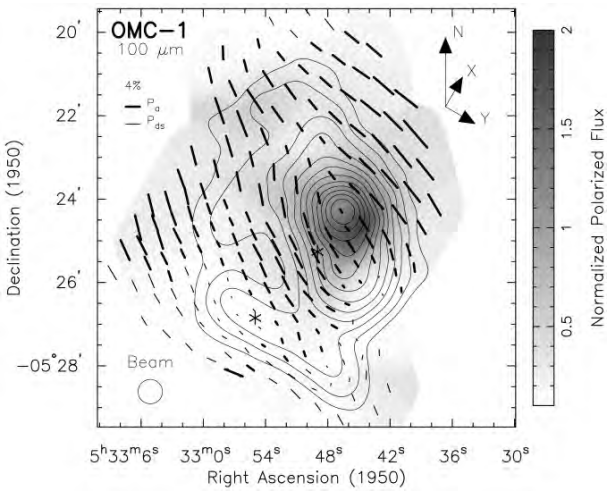

Figure 2. Geometry of the magnetic field in the OMC1 star formation region from 100 μm linearly polarized dust emission.

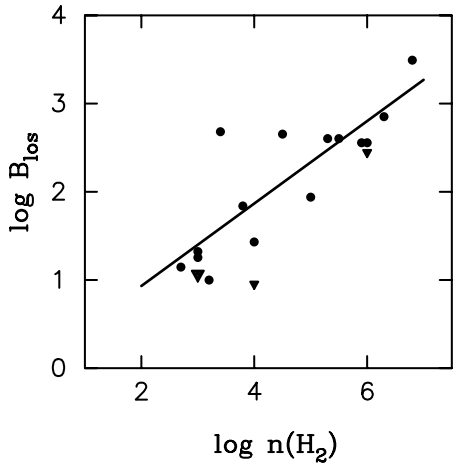

Figure 3. Relationship between magnetic field strength and gas density in self-gravitating molecular clouds.

90°, which may be due to a twisted magnetic field or to Gold alignment in the outflow from the core. However, the main geometry of the field is perpendicular to the minor axis of the cloud, which is expected if the tension of the uniform field is providing significant support against gravity.

The crucial parameter for evaluating the importance of magnetic fields in star formation is the ratio of the mass to the magnetic flux, M/Φ_B. Theoretical values for M/Φ_B (see also MAGNETIC FIELDS IN STARS) come from detailed computer simulations of interstellar clouds threaded by magnetic fields. The critical value of M/Φ_B is

$$(M/\Phi_B)_{\rm critical} \approx 1/(63\ G)^{1/2}.$$

Clouds that are initially magnetically supercritical ($M/\Phi_B > (M/\Phi_B)_{\rm critical}$) will collapse on relatively short time scales unless there is some other support mechanism. If the magnetic field was insufficient to stop the initial collapse, its compression during collapse cannot bring the cloud into equilibrium and halt the collapse. On the other hand, an initially magnetically subcritical ($M/\Phi_B < (M/\Phi_B)_{\rm critical}$) cloud will become unstable in its core owing to ambipolar diffusion. Only ions are frozen into the magnetic field, while the neutral material (by far the majority of the mass) can contract gravitationally unaffected directly by the magnetic field. However, neutrals will collide with ions in this process. This frictional force will provide support against gravity to the neutrals, but there will be a drift of neutrals into the core without a significant increase in the magnetic flux; this is ambipolar diffusion. Eventually M/Φ_B in the core becomes supercritical, and dynamical collapse and star formation can proceed.

M/Φ_B can be determined empirically from the magnetic field strength and the column density. Since

$$M = 2.8N(\mathrm{H_2})m_{\rm H} \times A \text{ and } \Phi_B = BA,$$

$$\frac{(M/\Phi_B)_{\rm observed}}{(M/\Phi_B)_{\rm critical}} = \frac{2.8N(\mathrm{H_2})m_{\rm H}(63\ \mathrm{G})^{1/2}}{B}$$

where A is the surface area of a cloud over which $N(\mathrm{H_2})$ and B are determined.

The role of magnetic fields may also be investigated with the virial theorem (ignoring possibly important terms such as surface pressure):

$$\mathcal{W} + 2\mathcal{T} + \mathcal{M} = 0$$

where the gravitational, kinetic, and magnetic virial terms respectively are:

$$\mathcal{W} = -\tfrac{3}{5}aGM^2/R$$

$$\mathcal{T} = \tfrac{3}{2}M\sigma^2$$

$$\mathcal{M} = \tfrac{1}{3}b|\boldsymbol{B}|^2R^3.$$

For the simple case of a uniform-density sphere, $a = b = 1$. A flattened, centrally condensed geometry will cause $a > 1$. For magnetically critical simulation models, $a \approx 1.2$ and $b \approx 0.3$.

Measurements of magnetic field strengths in molecular clouds depend on detection (and sometimes mapping) of the Zeeman effect in molecular lines (although when atomic hydrogen comes from photodissociation of H_2 near H II regions, the H I line may trace molecular gas). Most molecular Zeeman detections and sensitive limits have been in the 18 cm ground-state Λ doublet lines of OH. However, the OH radical probably does not trace densities above $n(\mathrm{H_2}) \sim 10^4$ cm^{-3} in most cases. An exception is Λ doublet OH lines that arise in excited rotational states, which require high gas densities for collisional excitation. Recently, detections of the Zeeman effect have been achieved toward the OMC1 and DR21(OH)

cores in the 3 mm lines of CN, which sample densities $n(H_2) \sim 10^{5-6}$ cm^{-3}.

To date, there have been 15 measurements of $B_\parallel$ in self-gravitating molecular clouds and an additional 12 sensitive upper limits, mainly in extended dark clouds with $n(H_2) \sim 10^3$ cm^{-3}. All 27 results are shown in figure 3. The data show a clear correlation of $B_\parallel$ with $n(H_2)$; the large scatter is due partially to the fact that only one component of $\boldsymbol{B}$ is observable. For $n(H_2) > 10^3$ cm^{-3}, the data are consistent with $B \propto n^{1/2}$, a result in agreement with theory.

A statistical analysis of the Zeeman results yields $(M/\Phi_B)_{\rm observed} \approx 1 - 2(M/\Phi_B)_{\rm critical}$. Thus, magnetic fields are sufficiently strong to play a significant and perhaps crucial role in the support of molecular clouds and in their evolution. The analysis in terms of the virial theorem yields the result that kinetic and magnetic energies are approximately the same, and clouds are in approximate virial equilibrium.

Gas velocities in molecular clouds are generally supersonic by a factor of a few but are approximately equal to the Alfvén velocity $(B/(4\pi\rho)^{1/2})$, which suggests that internal motions are due to MAGNETOHYDRODYNAMIC (MHD) WAVES. Although MHD waves might be expected to organize supersonic motions and significantly lengthen the dissipation time scale, recent supercomputer simulations suggest that Alfvén waves will dissipate on a time scale not much longer than that of non-magnetic turbulence. The rate of star formation may be regulated by the ambipolar diffusion rate and by the rate of injection of mechanical energy into clouds. Photoionization could play an important role, since the ambipolar diffusion rate would depend strongly on the ionization rate. Despite the constant dissipation of the turbulent energy, it may be continuously re-generated by the winds of stars that form inside the clumps and by torsional Alfvén waves that also transport angular momentum outward.

Theories of bipolar winds from YOUNG STELLAR OBJECTS often include a significant role for the magnetic field. Figure 4 shows an example of the use of linearly polarized spectral-line emission to map the geometry of magnetic fields in the CO bipolar flow from the NGC1333 IRAS4 region. The flow is initially at a small angle to the field, but the magnetic field appears to deflect the flow so that it becomes parallel to the field.

Future work

Our understanding of the interstellar magnetic field and its role in the formation of interstellar clouds and in star formation is still very incomplete. New telescopes (such as the upgraded Arecibo telescope, the Green Bank telescope, the Atacama Large Millimeter Array and the Stratospheric Observatory For Infrared Astronomy) should produce an explosion of new and improved data during the next decade. Comparison of these data with the detailed simulations of the interstellar medium and of star formation regions that advances in computer technology are enabling should be a focus of future research.

Interstellar Matter

The enormous volume of space between the stars in the Milky Way Galaxy is filled with interstellar matter (ISM). The ISM plays a central role in the processes of STAR FORMATION and GALAXY EVOLUTION. Stars form from the ISM in dense molecular clouds. The radiant and mechanical energy produced by stars heats, ionizes, and produces structures in the ISM. Gradual or catastrophic mass loss from stars enriches the ISM in heavy elements and causes the composition, distribution, and physical state of the ISM to change as the galaxy evolves. Current studies of the ISM are aimed toward characterizing its basic properties, determining the physical processes that control these properties, and establishing the role the ISM plays in the evolution of the Galaxy.

The existence of matter between the stars was first proposed by WILHELM STRUVE in 1847 based on an analysis of star counts which suggested that the number of stars per unit volume decreases with distance from the Sun. Struve proposed that the starlight was experiencing absorption proportional to distance. It was not until 1909 that Kapteyn realized the full significance of this interstellar extinction. Shortly later Barnard documented through direct imagery the irregular variations in the distribution of the absorbing matter. The identification of the source of the extinction with small particles of interstellar dust was finally accepted in the 1930s through the work of Trumpler and Stebbins, Huffer, and Whitford.

Diffuse emission nebulae powered by O stars with $T > 30\,000$ K were the component of the ISM first observed spectroscopically by astronomers The spectrum of the brightest example, the Orion nebula, was recorded in 1863 by Huggins. In the late 1920s Eddington, Zanstra and Bowen were able to show that such emission nebulae were clouds of ionized interstellar hydrogen containing He and trace amounts of heavier elements.

Absorption by interstellar Ca^+ in the interstellar gas was first spectroscopically recorded by Hartmann in 1904. However, it was not until the early 1930s that Plaskett and Pearce obtained extensive surveys of Ca^+ absorption in a large number of stars and convincingly associated the absorption with gas between the stars. They showed that the strength of the Ca^+ absorption increased with distance and that the absorption line radial velocity varied with distance and direction according to that expected from a simple model of gas rotating in a disk galaxy.

In more recent times the full diagnostic power of observations across the entire electromagnetic spectrum have been used to study emission and absorption produced by interstellar gas and dust in order to determine its composition, distribution, and physical state.

Components and composition

The ISM (gas + dust) in the solar vicinity has Population I element abundances. This has been established through abundance studies of the gas in diffuse emission nebulae (see GASEOUS NEBULAE), optical and ultraviolet absorption line studies of gas in neutral hydrogen regions, and by inference from studies of the composition of matter in the atmospheres of young O and B stars that have recently formed from the ISM. The ISM gas phase composition by relative number of atoms is 91% H, 9% He, and a trace abundance of the heavier elements.

Given the great abundance of H and He in the gas, much of the physics of the ISM involves interactions among these atoms, electrons, and photons. The H can exist as H^0, H_2, or H^+ while the He can exist as He^0, He^+, or He^{2+}. Absorption of radiation by H and He plays a dominant role in determining the nature of the average radiation field in interstellar space. In a neutral hydrogen region the strong H I absorption at the 13.6 eV Lyman edge results in an average radiation field resembling that of A and B type stars for $3 < E < 13.6$ eV with a greatly reduced intensity for $E > 13.6$ eV from H I absorption. At energies between ~3 and 1 eV the interstellar radiation field is dominated by the light from G and K stars.

The ionization state of the heavier elements in an H I REGION is determined by the ionization potential of the element compared to 13.6 eV. As a result, the abundant heavy elements listed in order of decreasing abundance O, C, Ne, N, Mg, Si, Fe, and S exist in the ionic states O^0, C^+, Ne^0, N^0, Mg^+, Si^+, Fe^+, and S^+. In H II REGIONS where the H I is photoionized by radiation from stars with $T > 30\,000$ K, the heavier elements are in higher states of ionization, e.g. O^+, O^{2+}, C^{2+}, C^{3+}, etc, with the actual ionic ratios controlled by the ionizing radiation field of the star. In the hot ISM where the gas is heated to $T > 10^6$ K by shock processes, the heavy elements exist in high states of ionization created by electron collisions. Therefore, elements such as O and C will exist as O^{6+}, O^{7+}, C^{6+}, and C^{7+}, with the actual ionic ratios determined by the kinetic temperature of the electrons (see INTERSTELLAR CHEMISTRY). A study of these very different gas phases requires observations in the radio, infrared, optical, ultraviolet, extreme ultraviolet and x-ray regions of the spectrum.

The gas phase abundances of HEAVY ELEMENTS in H I regions are reliably measured by ultraviolet absorption line spectroscopy toward hot stars. The line of sight column densities of H I and H_2 can be measured via the H I Lyman series absorption lines and the H_2 Lyman band absorption in the far-ultraviolet (see LYMAN ALPHA ABSORPTION). The metal line column densities can be determined from the many resonance line absorption transitions found in the ultraviolet. The results of these studies with the Copernicus Satellite (1972–1980) and more recently the Goddard High Resolution Spectrograph (1990–1997) aboard the Hubble Space Telescope (1990–) reveal that many of the heavy elements have gas phase abundances substantially less than Population I abundances because of the incorporation of the heavy elements into solid particulate matter. This effect is referred to as element depletion. For sight lines through moderately dense clouds in the galactic disk, the highly refractory elements such as Fe, Cr, and Ni have gas phase abundances reduced by factors of 100 to 200 while for other

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

elements, such as S, P, and Zn, the gas phase abundances are only reduced by factors of several. Si, Mg, and Mn exhibit intermediate reduction factors ranging from 10 to 30.

A detailed study of elements both missing and present in the gas phase of the ISM provides important indirect information about the presence or absence of those elements in interstellar dust. It is found that there is a general progression toward increasing gas-phase abundances of the depleted elements from cool neutral clouds found in the galactic disk to warm neutral clouds in the disk to warm neutral clouds in the galactic halo at distances away from the mid-plane of up to 1 kpc. This progression provides information about the destruction of dust grains in those processes that transport matter between these different galactic regions.

The INTERSTELLAR GRAINS can also be studied via their emission, scattering, and absorption properties. Approximately 1% of the mass of the ISM is in the form of interstellar dust. The most abundant particles consist of solid silicate grains and a separate carbon component which may be in the form of graphite grains. The silicates have been spectroscopically identified through infrared emission and absorption features at 9.7 and 18 μm while the graphite grains may be responsible for the 217.5 nm interstellar extinction bump. The grains likely have a distribution of sizes ranging from very small up to several μm in diameter. In the denser interstellar regions the grains can accrete atoms which form mantles on the grain cores. In the densest regions, mantles of H_2O ice are detected through an infrared absorption feature near 3.1 μm. The grains can affect the intensity of the interstellar radiation field though the extinction they produce, especially in dense interstellar regions. By locking up heavy elements from the gas the grains remove important coolants from the ISM. The grains also have significant roles in several interstellar processes including molecule formation and the heating of the gas through both molecule formation and photoelectric heating. The most abundant molecule observed in interstellar space, H_2, forms on the surfaces of grains. The dust also likely includes a population of very small grains, the PAHs or polycyclic aromatic hydrocarbons, which consist of planar molecules of combined benzene rings with attached H atoms. These particles have nm sizes and may represent the dividing line between large molecules and small particles. The PAHs are the leading candidates for a number of infrared emission bands.

High-energy (10^6–10^{20} eV) COSMIC RAYS exist in the space between the stars. Cosmic ray protons are most abundant with $n(\mathrm{p}) \sim 10^{-10}$ cm^{-3} and $n(\mathrm{e})/n(\mathrm{p}) = 10^{-2}$. The cosmic ray electrons have lower abundances than protons because they lose their energy more rapidly than the protons through the production of galactic non-thermal synchrotron radiation. Cosmic rays are $\sim 10^6$ times over abundant in various light elements because of cosmic ray spallation collisions of protons with heavier nuclei. Although the cosmic rays have a very low particle density, they can have substantial effects on the physical state of the thermal gas in the ISM through the processes of cosmic ray ionization and heating. Cosmic ray collisions with the gas also produce galactic γ-rays. Cosmic rays interacting with the galactic magnetic field may have important dynamical consequences. For example, the pressure of cosmic rays may play a role in the support of the gas found in the galactic halo.

The galactic general magnetic field in the solar region of the Galaxy has an average absolute strength of $\sim 5 \times 10^{-6}$ G. It contains an ordered component and an irregular component of roughly comparable strength. High-energy cosmic ray electrons spiraling in the galactic magnetic field produce non-thermal SYNCHROTRON RADIATION. Spinning dust grains are aligned by the magnetic field which leads to the observed interstellar polarization of starlight. The magnetic field has considerable dynamical effects since its pressure ($B^2/8\pi$) is comparable to the interstellar gas pressure. In dense interstellar regions the magnetic field strength is greatly amplified. Theories of the processes causing the collapse of an interstellar cloud into a protostar must involve a consideration of the dynamical consequences of the INTERSTELLAR MAGNETIC FIELD. On the larger scales, loop like galactic interstellar structures may be dynamically controlled by magnetic fields.

The different interacting components of the ISM discussed above have comparable energy densities (and pressures). For example, the energy density of the ISM radiation field from 91.2 nm to 8 μm is $\sim$0.5 eV cm^{-3}, the cosmic rays have $\sim$1.5 eV cm^{-3}, and $B^2/8\pi$ for a magnetic field with $B = 5 \times 10^{-6}$ G is 0.6 eV cm^{-3}. Gas motions associated with turbulence and waves in the ISM are estimated to have an energy density of $\sim$1 eV cm^{-3}. The different thermal phases of the gas discussed in the next section have $P/k = nT \sim 3 \times 10^3$ cm^{-3} K which implies an energy density of 0.3 eV cm^{-3}. The similarity of these energy densities (and pressures) is probably not a coincidence but is suggestive of a strong interaction and resulting energy and pressure equipartition among these different components of the ISM.

Phases and physical conditions of the ISM

The conditions in the ISM deviate very significantly from those found in a gas in thermal equilibrium. The mean energy density of the ISM radiation field is $\sim$0.5 eV cm^{-3} which corresponds to the energy density of a Planck black body distribution at $T \sim 3$ K. However, the spectrum of the interstellar radiation field is produced by the integrated but diluted radiation from stars with temperatures ranging from $\sim$3000 to $\sim$30 000 K. The extremely dilute nature and spectral hardness of this radiation field causes huge deviations from conditions found in thermal equilibrium. In the ISM, the populations of atomic and molecular energy levels and of different states of ionization will not be determined by the temperature of the gas but from the actual dominating processes for populating and depopulating the given state. The temperature assigned to gas in the ISM only refers to the fact the gas particles have

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

a distribution of velocity reliably described by a Maxwell–Boltzmann distribution at a particular temperature. The existence of such a velocity distribution is caused by the overwhelming number of elastic compared to inelastic particle collisions in a gas consisting of mostly H and He. Thus, the temperatures given for various interstellar regions only refers to the kinetic temperature of the gas.

The ISM of the Milky Way contains separate gas phases with kinetic temperatures that are cold ($T \sim 10$ K), cool (100 K), warm (10^4 K) and hot (10^6 K). The different phases of the ISM are listed in table 1 with approximate properties given for each phase including the kinetic temperature, T(K), the representative physical density, $n(\mathrm{cm}^{-3})$, the volume averaged density, $\langle n(\mathrm{cm}^{-3})\rangle$, the exponential scale height above the galactic plane, h(kpc), and the very uncertain volume filling factor, f. Most of the mass of the ISM (∼80%) is contained in the confined and extended components of the neutral gas. The extended component of the warm ionized gas contains ∼15% of the mass and the very extended hot gas contributes ∼3% to the mass.

In molecular clouds the hydrogen is mostly molecular and cold ($T \sim 10$ K). The molecular clouds are traced by emission from CO and other molecules. Although the molecular clouds comprise a small fraction of the volume of the ISM, they are estimated to contain ∼50% of the mass of the ISM. Molecular clouds are not normally considered a 'phase' of the ISM since they are not in pressure equilibrium with the more widely distributed gas.

The cold neutral medium (CNM) contains H I and H_2 and is studied via 21 cm H I emission and absorption, and ultraviolet absorption by H I, H_2, and various heavy elements. With a temperature of ∼80 K and a physical density of ∼40 atom cm^{-3} the CNM occupies only ∼3% of the volume of the ISM in the galactic disk.

The warm neutral medium (WNM) produces H I 21 cm emission but weak absorption. It can also be studied via ultraviolet absorption line spectroscopy. With $T \sim 8000$ K and $n \sim 0.4$ cm^{-3} the WNM occupies a substantial fraction (∼35%) of the volume of the ISM in the galactic disk.

The warm ionized medium (WIM) has been studied through the optical emission lines of Hα, [N II], and [S II] it produces. Observations of radio wave dispersion in the direction of pulsars yields a direct measure of the line-of-sight value of the electron column density in the WIM. With $T \sim 8000$ K and $n \sim 0.2$ cm^{-3}, the WIM occupies ∼25% of the volume of the gas in the disk of the Milky Way. The power (∼10^{41} erg s^{-1}) required to maintain the ionization of the WIM is comparable to the total power input of all galactic supernovae or ∼15% of the ionizing radiation emitted by galactic O stars.

The hot ionized medium (HIM) contains gas with $T \sim 10^6$ K and $n \sim 3 \times 10^{-3}$ cm^{-3}. It is detected through its soft x-ray emission. Somewhat cooler hot gas associated with the HIM has been detected through highly ionized atomic absorption produced by O VI, N V, and C IV and by emission from C IV. The HIM has a very uncertain volume filling factor of 40 ± 25%.

The different gas phases probably exist in rough pressure equilibrium. Various techniques have been used to estimate the thermal pressure in the neutral phase of ISM. The pressures are most often reported as $P/k = nT$ (cm^{-3} K). In neutral interstellar regions containing C^0 a typical value of P/k is $\sim 3 \times 10^3$ cm^{-3} K. However, there are large deviations from this typical value, particularly in regions overpressurized by shock waves from exploding stars or from the winds of hot stars. Pressures are substantially elevated in H II regions where relatively dense gas is rapidly heated to $T \sim 8000$ K by the O stars that have recently formed. Such overpressurized H II regions expand outward as the gas in them tries to achieve pressure equilibrium with the general ISM. In dense molecular regions pressures are found to be much larger as a result of the self-gravity of the gas. The pressure in the ionized gas at distances of ∼1 kpc from the GALACTIC PLANE has been estimated to be ∼3000 cm^{-3} K. The rate of drop off of gas pressure at larger distances away from the galactic plane is not well determined.

The total pressure produced by all the components of the ISM must be capable of supporting the galactic gas layer. At the galactic mid-plane that weight per unit area requires a total pressure, P/k, of approximately 30 000 cm^{-3} K. The combined pressure contributions from the various components of the ISM (e.g. gas thermal pressure, magnetic pressure, cosmic ray pressure, gas turbulent pressure) must add up to this number. In regions of greatly elevated pressure such as in OB associations with frequent supernova explosions, the higher pressure may drive gas into the halo in a flow pattern sometimes referred to as a 'galactic fountain'. In such a flow, high temperature ($T > 10^6$ K) gas bursts out of the galactic plane into the halo, cools by adiabatic expansion, and eventually rains back onto the galactic disk as warm and cool infalling fountain clouds.

General distribution

The stirring of matter in the galactic disk by supernova explosions, stellar winds, cloud–cloud collisions and other processes causes the various phases of the ISM to extend different distances away from the plane of the Galaxy. The stratification of this 'galactic atmosphere' is roughly described by layers with exponential density distributions away from the galactic plane with scale heights $h \sim 0.1$ kpc for the cool clouds, ∼0.4 kpc for the warm neutral gas, ∼1 kpc for the warm ionized gas, and ∼5 kpc for the hot ionized gas. These scale heights have been determined by studying the fall off of $N(\mathrm{X}) \sin |b|$versus$|z|$ where $N(\mathrm{X})$ represents the column density of species X toward stars at galactic latitude b having different distances, z, away from the galactic plane. For cold neutral gas and warm neutral gas, ultraviolet observations of H I Lyman alpha and H_2 Lyman band absorption are used to obtain $N(\mathrm{X})$. For the warm ionized medium, the observations are of pulsar dispersion measure which is proportional to the

† Molecular clouds are not listed as a phase of the ISM since they are not in pressure equilibrium with the more diffuse gas. In molecular clouds the hydrogen is mostly molecular, $T \sim 10$ K, and $n > 300$ cm^{-3}.

line of sight electron column density. The ∼5 kpc extent of the hot phase has been traced by observations of highly ionized atoms such as C^{3+} and N^{4+} toward stars in the galactic disk and halo. The thick warm neutral gas layer is often called the Lockman layer while the warm ionized gas layer is called the Reynolds layer.

The ISM gas density distribution in the Galaxy exhibits a radial dependence. The mid-plane densities of H_2 in the ISM as traced by the CO molecule are greater for regions interior to the solar circle and appear to peak at a galactocentric distance R of approximately 5 kpc. In the outer Galaxy, the H I is observed to warp and flare. The warp is to positive values of b over the region $l = 70$–140° and to negative values of b over the region $l = 240$–300°. The warping and flaring in the outer Galaxy has been observed to extend over a region ∼10 kpc thick. The radial extent of the neutral H I in the Galaxy is roughly 30 kpc or more.

Structures

The various kinds of structures found in the interstellar gas provide important information about the many physical processes affecting the ISM. In the disk of the Galaxy the cool interstellar matter has a highly irregular cloud-like structure. Information about the extents and sizes of these clouds can be inferred from observations of dust extinction toward large numbers of stars and from observations of interstellar atomic absorption lines toward stars. While clouds of many shapes and sizes probably exist, the extinction data yield information about the average properties of clouds containing dust. A summary of those properties is given in table 2. INTERSTELLAR ABSORPTION LINE studies confirm the existence of ∼7 cool diffuse clouds kpc^{-1} along the lines of sight to stars within several kpc of the Sun. Extreme examples of the large clouds are the molecular clouds which often trace regions of active star formation. Molecular clouds have masses in the range 10^5–10^6 $M_\odot$.

In addition to these clouds found in the mostly neutral gas, the ISM contains numerous structures which illustrate the direct interaction between stars and the ISM. These include the photoionized H II or diffuse nebulae which are found in star forming OB ASSOCIATIONS and the associated REFLECTION NEBULAE which are evident when the stars illuminating the gas and dust are cooler than B2 and therefore do not have adequate amounts of Lyman continuum radiation to ionize the gas. Other examples

Table 2. Average properties of neutral interstellar clouds traced by dust.

	Diffuse clouds	Large clouds
$\langle E(B-V)\rangle$	0.061 mag	0.29 mag
Number (kpc^{-1})	6.2	0.8
Contribution to $\langle n(H)\rangle$	0.7 cm^{-3}	0.4 cm^{-3}
Diameter	4 pc	70 pc
$n(H)$ in cloud	40 cm^{-3}	10 cm^{-3}
Mass for spherical cloud	50 $M_\odot$	$6 \times 10^4 M_\odot$

are the SUPERNOVA REMNANTS and PLANETARY NEBULAE which trace the processes of violent and peaceful stellar death, respectively. The shock heating of the gas in the supernova remnants can create large volumes of hot gas that expands outward and eventually joins with the general ISM. The processes of both violent and peaceful stellar death provide a means to enrich the ISM in elements created at some stage in the interiors of the dying stars.

Energetic events occurring in the disk can create H I shells and H I supershells. The extensions of these structures into the halo may produce structures called worms and galactic chimneys. Some of these structures mark the sites of OB associations where the combination of multiple stellar winds and multiple supernovae create over-pressurized regions which can in some cases feed hot gas into the halo and leave behind H I shells and supershells.

The H I observed at intermediate velocity ($|v| = 30$–100 km s^{-1}) at high latitudes in the northern galactic hemisphere traces substantial amounts of gas in arch-like features. The high velocity H I clouds ($|v| > 100$ km s^{-1}) which cover ∼20% of the sky trace gas with a number of different origins, including gas stripped out of the Magellanic Clouds through tidal interactions with the Milky Way, galactic fountain gas, and perhaps infalling intergalactic gas. The recent discovery that the extensive high velocity cloud Complex C has a metallicity of 0.09 ± 0.02 Solar implies that the galaxy may still be accreting low-metallicity material which could be a remnant of the formation of the Local Group of galaxies.

In the galactic disk the ISM has a greater density in the galactic SPIRAL ARMS which are waves of enhanced density that move through the gas and the stars of the disk. Local examples of these spiral arms in the Milky Way are clearly traced by the young stars of OB associations and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the molecular clouds from which the stars have recently formed. The three most prominent sprial arms near the Sun are the Perseus Arm, the Local Arm and the Sagittarius Arm. These three sprial arms have widths of ∼1 kpc and are separated by ∼1.5 kpc. In between the spiral arms, the interarm gas has a lower density and is more smoothly distributed.

Near the galactic center there is a $\sim 10^9$ solar mass concentration of the ISM, mostly in the molecular form in an expanding ring of ∼200 pc radius. This expanding structure may have its origins in the explosive release of energy from the galactic center or from the dynamical effects of a stellar bar. The ISM in this highly disturbed molecular ring has much more extreme properties than found elsewhere in the Galaxy.

Controlling physical processes

The physical state and distribution of the different components of the ISM are controlled by a number of physical processes. Identifying the dominant (controlling) processes is an important goal of studies of the ISM. In many interstellar situations it is assumed that the populations of ionic states or atomic and molecular energy levels are not changing with time. Under such 'steady-state' assumptions an identification of the dominating processes allows for a determination of the basic properties of the gas. However, in situations where the time evolution is rapid the steady-state assumption may be invalid, in which case it is necessary to follow the full time-dependent evolution of the gas.

The ionization state of the interstellar gas in H I and H II regions is controlled by starlight photoionization balanced by radiative and dielectronic recombination. In H I regions the radiation is produced by the integrated radiation from stars which is strongly attenuated for $E >$ 13.6 eV by H I absorption. In an H II region one or more O stars are usually the dominant sources of the ionizing radiation. In the hot ISM the ionization is controlled by electron collisions followed by radiative and dielectronic recombination.

The equilibrium abundances of molecules in the ISM are controlled by the dominating molecule production and destruction processes. The most abundant molecule, H_2, forms on the surfaces of grains and in diffuse clouds is destroyed by the absorption of far-UV radiation between 91.2 and 111 nm in the Lyman and Werner absorption bands. Following the absorption into an excited molecular electronic state, the excited H_2 molecule undergoes radiative emission into a bound state of the ground electronic state or into the unbound vibrational continuum of the ground electronic state which results in dissociation. The dissociation process occurs ∼10% of the time. Once the H_2 has formed, it can react with heavy atoms in various molecular reaction chains to form many of the ∼100 different molecules found in dense interstellar clouds. The atom–molecule reaction process is greatly accelerated by the atomic ionization occurring in dense interstellar clouds penetrated by ionizing cosmic rays. The ion–molecule chemistry occurring in diffuse and dense clouds seems capable of explaining the existence of many of the molecules found in these clouds. In very dense interstellar molecular clouds the dissociating UV radiation is absent. This allows the molecular chemistry to proceed to the creation of very complex polyatomic molecules containing as many as 10–13 atoms. Interstellar grains also likely participate in the production of molecules other than H_2. For example, in addition to molecule production processes similar to the formation of H_2 on grain surfaces, the exposure of a grain with a complex icy mantle to a harsh environment may lead to the ejection of various complex molecules from the matter in the surface layers.

The equilibrium kinetic temperature of the gas is controlled by the important cooling and heating processes. In most interstellar regions the cooling is produced by collisional excitation of atomic fine structure levels followed by radiative deexcitation with the loss of the photon from the region. In H I regions electron or hydrogen collisional excitation of low lying states in C^+ and O^0 can lead to the production of the cooling transitions of C II at 157 μm and O I at 204 and 76 μm. In hotter H II regions where the colliding particles have more energy, the important cooling transitons occur as forbidden optical emission lines from O^+, O^{2+}, and N^+. In the H II regions surrounding hot stars, the dominant heating process is the difference in the relatively large kinetic energy liberated to the gas by ejected photoelectrons (mainly from H I) as compared with the energy of the recombining electrons. The heating processes are not as well understood for H I regions. Several possibilities include heating caused by the photoelectric ejection of rapidly moving electrons from grains, or the heating occurring as high-speed H_2 molecules are ejected from grain surfaces during the molecule formation process. In this ejection process a modest fraction of the H_2 energy of formation is available to eject the molecule from the grain with a substantial energy of motion.

Theories of the physical state of the ISM

Theories of the interstellar gas and dust in the galaxy must be able to explain the co-existence of the different observed phases of the ISM. Over certain ranges of conditions in the ISM, multiple gas phases can co-exist in rough pressure equilibrium. Multi-phase models of the ISM consider the various interactions occurring between the general ISM and the stars which form from the intersellar gas and subsequently heat and ionize the gas. Before the discovery of the hot ISM in the early 1970s, a two-phase model was developed by Field, Goldsmith, and Habing to explain the co-existence of a cool neutral phase with $T \sim 10^2$ K and a warm neutral phase with $T \sim 10^4$ K. This two-phase model of the ISM demonstrated that two thermally stable gas phases could exist at the same pressure, provided a thermally unstable phase occurred at an intermediate temperatures. With the discovery of the hot ISM with $T \sim 10^6$ K, the two-phase model of the ISM was extended into a three-phase model by McKee and Ostriker. In the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

three-phase model the dynamic third hot phase is created by the collective action of stellar winds and supernova explosions that shock heat large volumes of gas to high temperatures. This shock-heated high-temperature gas tries to achieve pressure equilibrium with the other gas phases and begins to cool by evaporating the matter contained in the warm and cool clouds. The hot gas can also cool by radiative emission and by adiabatic expansion into the halo, provided it can break out of the galactic plane.

In the three-phase model of the ISM the warm ionized gas can be explained as a ionized transition region between the warm neutral phases and the hot phases. The importance of this component of the gas was not fully recognized when the three-phase models of the ISM were first introduced. Although the warm ionized medium produces quite faint Hα emission over most of the sky, it radiates a very large total power of $\sim 10^{41}$ erg s^{-1}, which is equivalent to the total power of all supernovae or $\sim$15% the ionizing radiation produced by O stars.

The three-phase model of the interstellar gas has been developed into a detailed theory involving the interactions among the different gas phases, luminous hot stars, and various types of supernova explosions. The self-gravitating molecular clouds are not considered a phase in the three-phase model of the ISM since the gas they contain is not in pressure equilibrium with the other gas phases. One of the most uncertain aspects of the three-phase model of the ISM involves our knowledge of relative filling factors and the overall importance of the different phases. Estimates of the average filling factor of the hot gas in the disk of the Milky Way unfortunately currently range from $\sim$15% to $\sim$65%. It is disturbing to conclude this overview of the ISM by saying that even in 1999 we do not know which phase of the ISM fills most of the space between the stars in the disk of the Milky Way.

Bibliography

The classic text book, Spitzer L 1978 *Physical Processes in the Interstellar Medium* (New York: John Wiley) continues to be the fundamental reference on the physics of the ISM.

The text by Osterbrock D E 1989 *Astrophysics of Gaseous Nebulae and Active Galactic Nuclei* (Mill Valley: University Science Books) is the standard reference for the physics of interstellar gas in gaseous nebulae ionized by starlight or by collisional processes.

Physical processes occurring in the ISM are the topic of a symposium held in Grand Teton National Park, 1987 *Interstellar Processes* ed D J Hollenbach and H A Thronson Jr (Dordrecht: D Reidel)

The evolution of the ISM is discussed in the Astronomical Society of the Pacific Symposium 1990 *The Evolution of the Interstellar Medium* ed L Blitz (San Francisco: ASP Conf. Series vol 12)

Interstellar Molecular Clouds

A molecular cloud is a condensation of interstellar gas in which the atoms are bound together as molecules rather than existing as free atoms or ionized particles. All of interstellar and intergalactic space is filled with gas, albeit of low density compared with the best vacuums achievable in terrestrial laboratories. The state of interstellar gas is largely determined by its density and temperature, and molecular clouds are the coldest, densest phase of the interstellar medium. In a molecular cloud, the gas is typically overwhelmingly molecular with less than 1% in either the atomic or ionized states.

Molecules in the interstellar medium are identified by characteristic emission (or absorption) lines in their spectra. The frequencies of these lines can usually be measured to better than one part in a million, and the probability of a misidentification when two or more lines from a single molecule are detected is vanishingly small. Molecules can rotate around or vibrate along the interatomic axes defined by the chemical bonds; torsional modes also exist. It is the transition from one rotational or vibrational state to another of individual molecules that gives rise to the spectral lines of a molecular gas. Because each molecule consists of different atoms in a unique geometry, the spectral lines from each molecule are unique. The rotational and vibrational transitions occur primarily in the infrared and radio portions of the electromagnetic spectrum; thus molecular clouds are detected primarily by infrared and radio telescopes. Most of the molecules detected in the interstellar medium to date have been identified from lines at millimeter wavelengths, the high-frequency end of the radio portion of the spectrum.

Molecular clouds are the sites of all known STAR FORMATION in the Milky Way, and observations of other galaxies imply that star formation takes place in molecular clouds everywhere in the universe. Thus the Sun and the solar system were formed in a molecular cloud long since dissipated. Molecular clouds exist throughout the Milky Way and are found in most SPIRAL GALAXIES, but are not abundant in ELLIPTICAL GALAXIES. Molecular clouds are found to very high REDSHIFTS, in one case when the universe was less than 10% of its current age.

The state of the gas

The characteristic temperatures of molecular clouds are generally quite low, ranging typically from 5 K to 300 K. Most of the gas in molecular clouds tends to be at the low end of this range; the higher end is observed only in regions where the gas is locally heated. The temperatures can be inferred from the ratios of the strengths of the spectral lines from rotational states at different energies. The lower the temperature of a cloud, the more slowly the molecules rotate on average, and the stronger are the lines from low-lying rotational energy states. A typical median temperature for a molecular cloud in the vicinity of the Sun is about 10 K.

Molecular clouds are composed overwhelmingly of molecular hydrogen gas, H_2; 99.99% of the molecules by number in a molecular cloud are hydrogen. The density within a typical molecular cloud ranges from about 10^2 cm^{-3} to about 10^6 cm^{-3}, although higher densities are achieved in regions of active star formation. The median density of the molecular gas in a typical cloud near the Sun's position in the Milky Way is about 10^3 cm^{-3}, much greater than the 0.3 cm^{-3} median density of the ambient atomic gas. At the cold temperatures characteristic of most molecular clouds, H_2 does not emit or absorb radiation; thus its density is usually inferred indirectly from the presence of trace constituents such as carbon monoxide (CO). Observations of trace molecules indicate that it is collisions with neutral particles that excite the molecules into higher rotational states, but atomic hydrogen is too underabundant to produce the observed spectral lines; only H_2 is sufficiently abundant to produce the collisional excitation. Occasionally, a bright infrared source is observed in or behind a molecular cloud and the spectral lines of molecular hydrogen can be observed directly in absorption against the background source. In these cases, the quantity of molecular hydrogen observed is consistent with that inferred indirectly from the trace molecules.

In all molecular clouds there is an admixture of dust, typically about 1% by mass. When the dust becomes opaque to the ambient ultraviolet radiation, photons energetic enough to destroy the chemical bonds between the atoms of the gas are effectively prevented from entering a cloud. The dust radiates energy efficiently in the infrared portion of the spectrum, a wavelength regime to which molecular clouds are relatively transparent except in the densest regions. Thus, when molecules collide with the dust, the energy of the collisions heats the dust particles which then emit infrared radiation that escapes the molecular cloud. The dust therefore acts as an efficient thermostat keeping the cloud cold.

The formation of molecules in the interstellar medium

At the cold temperatures typical of molecular clouds, molecular hydrogen cannot form as the result of two hydrogen atoms directly colliding and binding together, because the excess energy of the collision cannot be radiated away. This is due to the symmetrical nature of H_2 which has no permanent electric dipole moment required for the radiation to take place. Thus H_2 is thought to form when hydrogen atoms attach themselves to the surfaces of the dust particles which are always present. The atoms migrate on the surface of the dust, bind together to form a hydrogen molecule, and the excess energy goes into heating the dust particle and ejecting the molecule from the surface. The dust thus plays a crucial role in the formation of molecular clouds: it provides the site for the formation of the H_2, it prevents the destructive ultraviolet radiation from breaking the chemical bonds

and dissociating the molecules, and it provides an effective temperature regulator that keeps the clouds cold.

Molecular hydrogen is not the only species thought to form on the surfaces of interstellar dust. The abundances of molecules that contain many heavy atoms, such as the complex organic molecules (see table 1), are too large to have formed from gas-phase attachment of carbon, nitrogen and oxygen. An important chemical pathway is thus thought to occur on the surface of dust grains and reactions that require the presence of dust as a catalyst are known collectively as grain-surface chemistry (see also INTERSTELLAR GRAINS).

Many other species, particularly molecules with only a few atoms, are thought to form directly in the gas phase without catalysis by dust. These are primarily through ion–molecule reactions, but reactions involving neutral radicals may also be important. A key ion–molecule reaction involves ionizing H_2 by COSMIC RAYS energetic enough to penetrate a molecular cloud producing H_2^+ which can subsequently bind with another hydrogen atom. The resulting H_3^+ ion is relatively abundant, highly reactive and the first step in forming many other molecules through exchange interactions with C, N and O in the gas phase. Molecules thought to form through ion–molecule reactions are CO, CH, H_2O and CH_4. Other chemical pathways result from relatively high-temperature reactions that occur in shocks, such as those produced in supernova explosions, and from high ultraviolet radiation fields such as those that occur in photon-dominated regions close to O and early B stars and relatively transparent diffuse molecular clouds.

The dust consists of molecules in the solid state and is composed primarily of atoms heavier than hydrogen, in the form of refractory (i.e. temperature-stable) and volatile compounds. The refractory compounds are primarily oxides of magnesium and silicon, and carbon compounds such as graphite, amorphous carbon (soot) and polycyclic aromatic hydrocarbons, large benzene-ring-based structures that contain admixtures of elements other than carbon. The volatile compounds on the dust surfaces are typically ices of water, ammonia, methane and other simple molecules that are composed of C, N, O and H. The dust particles are microscopic, with sizes that range up to about 1 μm (10^{-6} m) in diameter.

The composition of molecular clouds

Although molecular clouds are composed overwhelmingly of H_2, the molecule is not generally detectable for the same reason that the formation of H_2 from two gas-phase hydrogen atoms is prevented: the molecule lacks a permanent electric dipole moment. Other much less abundant molecules are, however, easily detected and the list of molecules detected in molecular clouds now totals about 120; a listing is given in table 1. These include carbon monoxide (CO), the most abundant molecule after H_2, water (H_2O) and many commonly known inorganic molecules such as ammonia (NH_3), hydrogen sulfide (H_2S), hydrogen cyanide (HCN) and common table salt (NaCl). The first organic molecule discovered in the interstellar medium was formaldehyde (H_2CO) in 1968. Since then, many organic molecules have been detected including formic acid (HCOOH), methanol (CH_3OH) and ethanol (CH_3CH_2OH), proving that the formation of organic molecules, including rather complex ones, occurs even in the relatively harsh conditions of interstellar space. Searches are now underway for glycine, the simplest of the amino acids, and buckminsterfullerene, C_{60}. Spectral lines consistent with origins in these and related molecules have already been detected, but positive identifications have not as yet been made.

Table 1 shows that the overwhelming majority of molecules are composed of H, C, N and O. This is due in part to the relatively high abundance of these elements compared with others, but also because the molecules formed from other heavy elements tend to produce refractory compounds that reside in the dust particles.

Because the density of the gas in molecular clouds is so low, highly reactive species such as radicals, molecules with unpaired electrons which have very low equilibrium abundances in terrestrial reactions, can be quite abundant in the interstellar medium. For example, OH, CH, CN are all easily detected. The radical HCO^+ was observed first in the interstellar medium and only later observed and confirmed in the laboratory. Some species such as $HC_{11}N$ have never been detected in terrestrial laboratories; their presence is inferred from the rotational constants determined from one observed transition and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the detection of other transitions at precisely predicted frequencies determined from these constants.

The abundance of CO is only 10^{-4} that of H_2, yet it produces extraordinarily bright spectral lines at wavelengths of 2.6 mm and 1.3 mm. High-energy transitions of this molecule have been detected into the far infrared portion of the spectrum from regions in which the temperature is inferred to be several hundred K. CO is a molecule that is excited at relatively modest densities and is even more tightly bound than H_2; consequently CO and H_2 are thought to be largely cospatial. The CO thus serves as a tracer for the undetectable H_2. Knowledge about the distribution of molecular clouds in the Milky Way and in other galaxies comes primarily from observations of the CO molecule (see also GAS IN GALAXIES). CO is, however, almost always optically thick, and direct inferences of the H_2 content from CO observations must be done with some care.

Masers

In most molecular clouds, the higher the energy of a rotational state, the fewer the number of molecules that occupy that state. Occasionally, conditions can arise in which there are more molecules in the higher energy state than the lower one, resulting in a condition known as a population inversion. If the cloud is transparent to radiation with an energy equal to the difference in energy between the states with a population inversion, the higher-lying molecules can be stimulated to emit radiation at a rate much higher than they would spontaneously, as they do in a laser. Such a region is known as a maser, an acronym that stands for microwave amplification by stimulated emission of radiation.

The radiation from regions within a molecular cloud that emit as masers can be extraordinarily bright; in fact the brightest known spectral lines in the radio portion of the spectrum come from interstellar masers. Many molecules have transitions that can behave as masers, but the most commonly observed ones are OH, H_2O, SiO, H_2CO and CH_3OH. The maser emission comes from regions that are typically quite small; for OH and H_2O masers, these regions are only as large as the solar system. However, because they are so bright, they can be observed to very large distances.

Masers have played an important role in astronomy because their motions make it possible to determine absolute distances with the aid of very long baseline interferometry (VLBI). For example, the only absolute determination of the distance to the center of the Milky Way has been done using statistical parallaxes of water masers in a molecular cloud, Sgr B2, thought to lie very close to the center. Similarly, the best measured absolute distance to another galaxy comes from a geometric distance measurement to the water masers in the disk of the galaxy NGC 4258. It is the extraordinary precision of VLBI positional measurements coupled with the very bright emission from the masers that make such determinations possible.

Properties of molecular clouds

Molecular clouds in the Milky Way have masses that range from a few times the mass of the Sun ($M_\odot$), to about $10^6 M_\odot$; molecular clouds with masses greater than $10^4 M_\odot$ are known as giant molecular clouds (GMCs). Along with the GLOBULAR CLUSTERS of stars, GMCs are the most massive individual objects in the Milky Way. The numbers of molecular clouds by mass can be described as a power law with an exponent of -1.5 ($\mathrm{d}N/\mathrm{d}M = N_0 M^{-1.5}$), which implies that most of the mass in molecular clouds lies at the high-mass end: more than half the total mass of the molecular gas in the Milky Way resides in clouds with masses $>10^5 M_\odot$. GMCs have typical diameters of about 50 pc, but many are quite elongated and GMCs observed in the solar vicinity often have extents as large as 100 pc.

GMCs are self-gravitating, i.e. they are held together by the mass of the molecular gas contained within them. This is inferred from the presence of star formation within GMCs, implying that at least part of a GMC must be self-gravitating, and from column density measurements that imply there is approximately enough gas to bind GMCs gravitationally. However, the best evidence that entire clouds are self-gravitating comes from measurements of the internal pressure within molecular clouds; these are invariably about 10 times the pressure of the ambient interstellar medium. If the clouds were not self-gravitating, they would rather quickly fly apart in about 10 million years.

Clouds with masses $<$ about $10^3 M_\odot$ are, however, often not self-gravitating. These clouds, known as high-latitude clouds (HLCs), were first found in abundance at large angles from the midplane of the Milky Way. They nevertheless lie at small distances from the plane as do all molecular clouds. These objects have now been found in profusion throughout the Galactic plane and, like the GMCs, have internal pressures much greater than the ambient pressure in the interstellar medium. However, unlike the GMCs, column density measurements show that the HLCs do not have enough mass to be self-gravitating, often by factors of 100 or more; and since their lifetimes must be very short their formation is a bit of a mystery. Presumably, they are formed in regions of relatively high interstellar pressure, perhaps in shocks; the ubiquity of these clouds implies that shocks are pervasive in the interstellar gas.

Molecular clouds are very inhomogeneous objects; median densities within the emitting regions are an order of magnitude larger than the density averaged over the entire volume of the cloud. Apparently, molecular clouds are organized into relatively smooth clumps of turbulent gas with higher than average density which fill only about 5–10% of the cloud volume. Stars form in the densest, most tightly gravitationally bound of these clumps, which are sometimes elongated into filaments. An alternative description suggests that the gas is organized in a fractal structure in which the distribution of density is the same regardless of the linear scale on which the cloud is

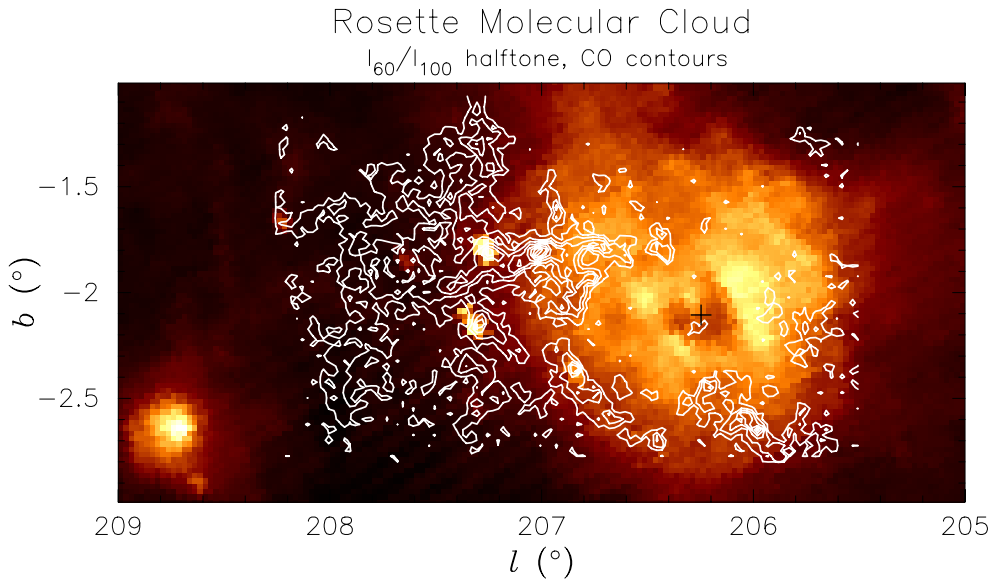

Figure 2. The Rosette Nebula molecular cloud, a good example of a Giant Molecular Cloud, is shown in the white contours, which trace the emission from CO. The infrared radiation from nebula is shown in the greyscale image as the bright region to the right of the main body of the molecular cloud. The absence of molecules toward the bright nebula is due to the dissociation of the molecules by ultraviolet radiation from hot stars in the center of the nebula (not seen in this image). (Credit: Jon Williams and Leo Blitz.)

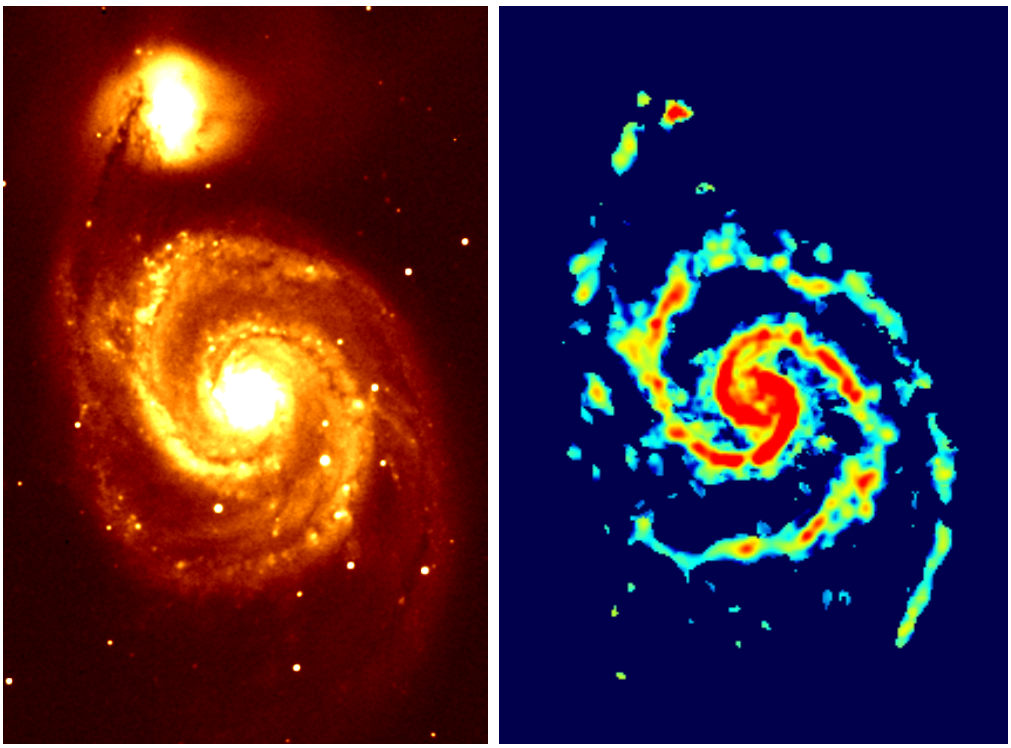

Figure 3. The left-hand panel shows an optical image of the Whirlpool Galaxy, M51, together with the small companion galaxy NGC 5195 in the upper left-hand portion of the image. The right-hand image shows the CO emission mapped with the BIMA Array from M51; the CO traces the molecular clouds in the galaxy. Note how tightly confined the CO emission is to the well-defined symmetric spiral arms in the galaxy. There is very little molecular gas between the spiral arms. (Credit: Stuart Vogel and the BIMA SONG collaboration.)

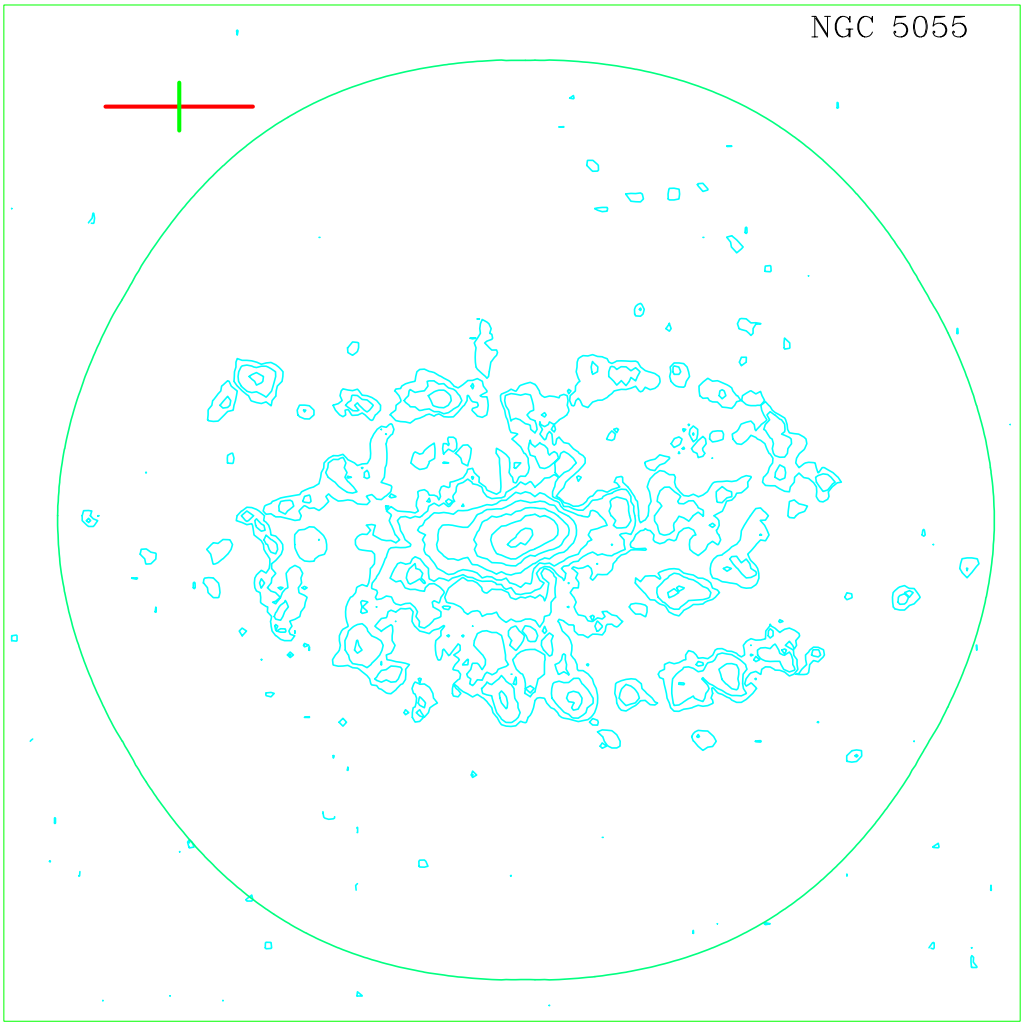

Figure 4. CO emission superimposed on an optical image of the flocculent spiral galaxy NGC 5055 mapped with the BIMA Array. The optical image shows only very short spiral arm segments. Although the CO emission shows evidence of some two-armed spiral structure, the spiral structure is much less pronounced than in M51. (Credit: Michele Thornley and the BIMA SONG Collaboration.)

observed. The fractal description appears to be more appropriate for the diffuse parts of a molecular cloud.

The formation process of GMCs is poorly understood. Although numerous mechanisms have been proposed, none has been shown to be primarily responsible for the formation of GMCs. In the disk of the Milky Way, it is thought that molecular clouds form by condensing from atomic hydrogen in regions where the atomic hydrogen has become self-gravitating and overdense; it has not been established what produces these regions of overdensity. Some other process, however, must be responsible for the formation of the small molecular clouds, the HLCs, because of their lack of self-gravity.

The molecular clouds in the nucleus of the Galaxy probably form by yet some other process. Within about 300 pc of the Galactic center, there is a strong concentration of molecular gas which has a surface density more than 100 times greater than that near the Sun. In this region, probably no more than about 1% of the neutral gas mass is atomic, and there is insufficient H I to condense into molecular clouds. The ambient gas pressure in this part of the Milky Way is almost 1000 times greater than that in the vicinity of the Sun, however, and it may be that gas clouds are stable at these pressures only if they are fully molecular.

Once formed, GMCs produce stars almost immediately. In the vicinity of the Sun only one GMC is known without intense star formation, and, in the Milky Way as a whole, no more than half of the GMCs are without massive stars forming in their midst. The star formation within a GMC sows the seeds of its own destruction because the high mass stars are intense emitters of ultraviolet radiation which dissociates the molecules, turning them back into ionized and molecular gas. The process of destruction is

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

quite rapid, and GMCs are thought to be transient objects with lifetimes no greater than about (30–50)$\times 10^6$ yr. The small HLCs are thought to live for even shorter times. Another argument for the short lifetimes of molecular clouds comes from their strong confinement to SPIRAL ARMS, observed in the Milky Way and in other galaxies. The confinement implies that the clouds cannot live longer than the time it takes to traverse a spiral arm, about 50 million years. A third observation from which the youth of molecular clouds is inferred shows that clusters of stars older than about 50 million years never have molecular gas associated with them; clusters younger than about 20 million years always have associated molecular clouds.

The internal structure of molecular clouds cannot be maintained without some source of energy injection into the clouds. Like stars, molecular clouds would all collapse under their own self-gravity if they were not supported by some means. Unlike stars, this support does not come from the temperature of the gas which is too low to produce the large widths of spectral lines observed throughout molecular clouds. The large line widths suggest rather that bulk motion of the gas, such as that from turbulence, is responsible for the line widths. However, such turbulence should decay in a very short time, typically less than 10^6 yr, unless there is some sort of energy that can maintain the turbulence within a cloud.

Magnetic fields, known to be present from the polarization of the dust, from polarization in the spectral lines, and from the Zeeman splitting of the spectral lines in masers, are thought to provide the necessary support and mediate the energy injection into the clouds. However, the strengths of the magnetic fields have not yet been measured in the gas that makes up most of the mass of molecular clouds. Nevertheless, magnetic field strengths of about 10 μG are inferred, for which the measured line widths would be at or below the Alfvén velocity. The star formation in molecular clouds is accompanied by energetic outflow activity which provides enough energy to maintain the support of the molecular clouds. Furthermore, the magnetic fields within molecular clouds may be tied to the fields in the general interstellar medium, and the explosions that take place there (such as by SUPERNOVAE) may be able to transfer some of their energy to the molecular clouds along magnetic field lines.

Star formation in molecular clouds

All known star formation takes place in molecular clouds, and the overwhelming majority is known to take place in GMCs. This is not surprising since most of the molecular gas resides in GMCs, but star formation in low-mass molecular clouds also has been observed. A region of active star formation known as the Eagle Nebula is shown in figure 1; the molecular gas (traced by CO) is seen to be closely confined to the columns of dust.

All stars younger than a few million years are either embedded within molecular clouds or close by, having recently been liberated from them. The youngest stars are still embedded within their nascent molecular clouds and are optically obscured by the associated dust in the densest portions of a molecular cloud. These stars are not visible optically and can only be seen with INFRARED TELESCOPES. The most massive young stars, the O stars, form together with stars of lower mass and produce regions of highly ionized emission called H II REGIONS; the brightest of these are always found still associated with the molecular clouds from which the O stars formed. This radiation, along with ionizing winds from these O stars, can dissociate and ionize the molecular gas and is the likely cause of the dissolution of molecular clouds.

An example of a molecular cloud–H II region combination is shown in figure 2, which shows the well-known ROSETTE NEBULA and its associated GMC. In the middle of the bright nebula are five O stars that provide the ionizing radiation causing the H II region to fluoresce. The mean density of the H II region is very nearly equal to the mean density of the molecular cloud and is considerably higher than the density of the surrounding gas. The molecular cloud was, therefore, presumably much larger and was ionized by the O stars in the nebula itself. A new generation of stars is forming deep within the molecular cloud.

GMCs have substructure, with most of the mass residing in clumps of gas which are manifested as well-defined regions within a GMC that have a coherent velocity, and are separated from other clumps both spatially and in velocity. The mean density within the clumps is typically about 500–1000 cm^{-3}, and the mean density averaged over the volume of a GMC is only about 50 cm^{-3}. Thus the clumps take up only about 5–10% of the volume of a GMC. Star formation takes place only in the clumps that are the most tightly gravitationally bound and, within these, only in the densest regions in the central parts of the clump. Within the clumps are yet denser regions known as cores that give rise to individual stars or binaries. The degree to which the cores are separate entities from the clumps, and the way that the cores separate from the clumps, is a matter of current research. However, stars tend to form in groups, clusters or associations and, by implication, there must be many cores within a typical clump.

Cores have typical densities of $\sim 10^5$–10^6 cm^{-3} and can be observed in a variety of molecules. Some cores already have stars or protostars (stars still in the process of formation) within them, but some appear to be in an earlier stage of formation and are starless. The cores that form low-mass stars (stars with masses comparable with the Sun) have masses comparable with what would be produced by a Jeans instability for gas at about 10 K. For such an instability to produce a star, however, the core must lose its magnetic support. This is thought to take place by ambipolar diffusion, diffusion of the magnetic field along the field lines, but other processes, such as MAGNETIC RECONNECTION, may also play a role. Once collapse begins, it is thought to take place from the inside out, with the central regions collapsing first. Material with low angular momentum falls onto the central star, and

material with a larger angular momentum is thought to form a disk. Observational evidence for disks around low-mass stars is quite conclusive. The disks are the material from which planets similar to our solar system form. The formation of a low-mass protostar also generally gives rise to jets which can sometimes be observed in the optical and infrared portions of the spectrum and resemble the jets seen in quasars and radio galaxies, but with much lower energies. These jets can accelerate the ambient molecular material forming bipolar outflows which are very common in regions of active star formation. These outflows may be the source of much of the support of molecular clouds.

High-mass star formation is likely to proceed differently because, once the highest-mass stars form, they rapidly produce regions of ionized gas known as H II regions, which are energetic enough to destroy a molecular cloud. Thus it is generally supposed that the highest-mass stars appear only after the low-mass stars have substantially formed. The cores that form high-mass stars have not yet been conclusively identified, but this is likely to be the result of observational bias. High-mass star formation is thought to take place very rapidly, and once a high-mass protostar has formed it almost immediately affects the region in its vicinity. It therefore becomes difficult to disentangle the properties of pre-existing cores that form high-mass stars from the effects of a previously formed star.

Molecular clouds in galaxies

Molecules have been observed in galaxies beyond the Milky Way since 1975. The great distance of these galaxies makes it difficult to resolve individual molecular clouds in any but the nearest galaxies: the MAGELLANIC CLOUDS, M31 and M33. Nevertheless, much has been learned about molecular clouds in other galaxies, largely from observations of CO and a few other molecules such as HCN, CS, H_2O and OH.

Spiral galaxies are known to be much more abundant in molecular gas than elliptical galaxies; only a handful of elliptical galaxies are known to have molecular gas. Elliptical galaxies are known to be gas poor in general, so the paucity of molecular gas is not surprising. IRREGULAR GALAXIES, although generally gas rich, generally have relatively weak CO lines, but, since these galaxies usually have a relatively low abundance of heavy elements, the paucity of CO may not be indicative of a relative absence of H_2.

Spiral galaxies exhibit a plethora of morphologies in the molecular gas, with CO sometimes clearly outlining the spiral arms, as is seen in figure 3 for the galaxy M51, and sometimes no spiral arms are evident as is seen for NGC 5055 in figure 4. The surface density of molecular gas is sometimes seen to increase right into the nucleus, but sometimes the nucleus is devoid of molecular gas as is the case in M31. Galaxies which appear to be morphologically similar in the optical portion of the spectrum may have very different morphologies in the molecular gas. These differences have only recently been recognized because the resolution and sensitivity necessary to make high-resolution images of the molecular gas have only recently been achieved through millimeter-wave interferometry.

By analogy with the Milky Way, stars in other galaxies are thought to form where the molecular gas is bright and therefore abundant. This is confirmed by the presence of H II regions and strong infrared radiation from embedded stars, both of which trace recent star formation, coincident with the molecular clouds in the galaxies. Although there are large variations of the star formation rate in the molecular gas both from galaxy to galaxy and even within a galaxy, there is generally a good correlation of indicators of star formation with molecular gas.

In the nuclei of some galaxies known as STARBURST GALAXIES, the rate of star formation is 10–100 times the rate of star formation in a normal galaxy. All starbursts are rich in molecular gas and have large quantities of molecules such as HCN, CS and HCO^+, all of which are indicators of relatively dense gas. Evidently, starbursts occur when extraordinarily large quantities of molecular gas are transported into the nucleus of a galaxy, which then becomes unstable to rapid star formation. In general, it is only possible to trace the formation of high-mass stars in these systems and the total star formation rate is generally inferred by assuming that the mix of stars that is formed is similar to that in the Milky Way. Starburst galaxies, and their spectacular cousins the ultraluminous galaxies, are usually the product of interactions and mergers of two galaxies. Simulations suggest that the molecular gas plunges into the center in the process of merging, which may explain how such a large quantity of gas is brought to the nucleus so quickly (se GALAXIES: INTERACTIONS AND MERGERS).

Galaxies also sometimes have 'active' nuclei, in which explosive events are thought to be energized by a BLACK HOLE. That is, in falling into a black hole, energy is liberated which can strongly heat gas to produce very high expansion velocities, highly excited atoms and jets of material expelled from the nucleus. One class of these galaxies is known as SEYFERT GALAXIES, after their discoverer, Carl Seyfert, the nuclei of which are thought to be surrounded by tori of molecular gas which provide the fuel for the nuclear activity. These tori, although widely expected, have not yet been observed because the resolution of the observations has not yet been available. The molecular clouds in the circumnuclear tori are probably quite different from the molecular clouds observed in the disk of the Milky Way.

Molecular gas has also been observed toward the edge of the observable universe in some of the highest-redshift galaxies yet observed. One galaxy with a redshift of 4.7 is known to contain vast amounts of CO at a time that the universe was less than 10% of its current age. A number of galaxies with redshifts between 1 and 4.7 have been detected and there is a great deal of interest in both finding more GALAXIES AT HIGH REDSHIFT and observing them in detail. The detected galaxies exhibit huge bursts of star formation and can tell us a great deal about the early formation of stars and the evolution of galaxies.

Intracluster Medium

With the expression 'intracluster medium' (ICM) one indicates the material other than ordinary galaxies present in clusters of galaxies. The presence of the ICM is inferred from direct observations and indirect evidence. In 1951, a famous paper by F ZWICKY on the morphology of the COMA CLUSTER of galaxies in the northern hemisphere reported his discovery of a diffuse light in the region between galaxies belonging to the Coma cluster: '*. . . vast and often very irregular swarms of stars and other matter exists in the spaces between the conventional spiral, elliptical, and irregular galaxies*'. Following Zwicky's initial discovery of the presence of an intragalactic matter made up from stars, in 1966 a source of x-rays was detected in the VIRGO CLUSTER and was followed by detections in the Perseus cluster and in the Coma cluster itself in 1971. Since then, several x-ray satellites have observed nearly hundreds of clusters showing that indeed they are bright sources of x-rays. The observations in the optical wavelengths and the x-ray detections indicate that the clusters of galaxies contain an ICM and this material is present in two phases: a diffuse stellar component, irregularly distributed, and a hot tenuous gas that fills the cluster more or less homogeneously. Indirect evidence for the presence of an unseen component in clusters of galaxies comes from the application of the virial theorem to the observed velocity dispersion of galaxies in clusters: for the cluster to be in equilibrium an additional component other than galaxies, the hot gas, and diffuse star light, must be present to keep the clusters bound.

Properties and origin of the diffuse light

The first observations of the diffuse light associated with the ICM in clusters of galaxies were based on photographic techniques, followed recently by observations with CHARGE-COUPLED DEVICES (CCDs). Several difficulties affected these earlier studies. Photographic plates do not have an homogeneous response through them (and this behavior cannot be accounted for during the data analysis as is done for images acquired with CCDs) and typically the surface brightness of the intracluster light is less than 1% of the night sky brightness. In addition there is scattered light from bright objects, the contribution from discrete sources—dwarf or irregular galaxies—below the detection limit, and clusters extend over large areas on the sky: nearby clusters such as Virgo or FORNAX cover an area of several square degrees (the image of the Moon or the Sun covers half a square degree on the sky) while linear detectors such as CCDs cover a much smaller area (of the order of hundreds of square arcminutes) and mosaicing is required. Furthermore, at the position of cluster centers one normally finds a giant elliptical galaxy with an extended halo of stars: these objects are classified as cDs, i.e. cluster dominant galaxies. In these cases it is difficult to disentangle the diffuse light associated with the halo of the cD galaxy and the ICM diffuse stellar component. The best estimate based on these observations for the diffuse light component of the ICM is that its contribution is 10–50% of the total cluster light in galaxies, in a region between 200 h^{-1} kpc and 450 h^{-1} kpc from the central cD galaxy (here the HUBBLE CONSTANT is written as 100 h^{-1} km s^{-1} Mpc).

An alternative method for probing intracluster star light in the ICM is through the direct detection and measurements of the stars themselves. In the 1970s a line of attack to track down the debris making up the diffuse light in the ICM was to look for intergalactic supernovae, but these studies reported a negative answer for the Coma cluster, while an intergalactic supernova was detected in 1981 in the Virgo cluster. In the 1980s another suggestion was that the cD galaxies in clusters might be surrounded by a population of globular clusters stripped from their parent galaxies: there are now suggestions that the pronounced globular cluster overabundance of some galaxies at the centers of galaxy clusters is best explained by assuming the existence of a population of intergalactic globular clusters.

Very recent observations have shown that direct detection of individual stars in the ICM is possible. Studies of the ICM in the Virgo and Fornax clusters have detected several hundreds of point-like emissions from individual stars in their post-AGB phase of PLANETARY NEBULAE. The planetary nebulae are very easy to detect because their nebular outer shell encircling the central star emits nearly 15% of the total energy from the central star in the [O III] emission line at 5007 Å: by simply taking an image through a narrow-band filter centered at the planetary nebulae redshifted [O III] emission and in its adiacent continuum, it has been possible to identify nearly a hundred planetary nebulae emissions in nearby clusters. Simulations based on the overall number of detected planetary nebulae emissions and the properties of their luminosity function in early-type galaxies indicate that the diffuse stellar component in the ICM can contribute up to 50% of the total light emitted by galaxies in the Virgo and Fornax clusters.

Independent evidence for the presence of stars in the ICM comes from observations carried out with the HUBBLE SPACE TELESCOPE. These observations have detected red-giant-branch stars (stars nearly 13 Gyr old) in a Virgo cluster field centered 235 kpc east of the galaxy NGC 4486, placed at the center of this cluster. The excess star number counts in this surveyed field with respect to a control field and calibrations based on well-known luminosity profiles of elliptical galaxies (which have a population with similar age and color to the intergalactic stars detected with the Hubble Space Telescope) indicate that the diffuse light in the ICM contributes nearly 10% of the stellar mass in Virgo cluster galaxies.

The discrepancy between the detections based on the [O III] line emission from planetary nebulae, observed in the region of the Virgo cluster core, and the red number count excess may be related to a strong inhomogeneity in the distribution of the stellar component of the ICM. The detailed spatial distribution of this diffuse stellar component is not known yet on the Mpc scale (typical radius for a cluster of galaxies is nearly 3 Mpc), and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

its distribution may be related to the origin of this ICM component itself. Tidal interactions between galaxies in a cluster are expected to be frequent and cause galaxies to lose a substantial fraction, 30–70%, of their stars to the cluster potential where they become the stellar component of the ICM. Because this diffuse component would then originate from tidal tails, one expects its spatial distribution to be quite inhomogeneous. The debris can be relaxed in the cluster core but the further out one goes, the more unrelaxed the population might become.

Large CCDs, mosaiced detectors and observations with the Hubble Space Telescope will soon address these questions and give more information on the origin of this component of the ICM. The discovery of single stars in the ICM gives an opportunity to detect the local cluster mass-over-light ratio at the positions where they are identified, and have strong implications on the baryonic content of clusters and the origin of the hot gas phase in the ICM.

Properties and origin of the hot gas

The x-ray hot gas is the main '*visible*' component of clusters of galaxies: its total mass varies from 1 (*groups*) to 7 (*rich clusters*) times the stellar mass present in cluster galaxies and it can reach up to 30% of the total cluster mass—visible plus dark matter. The gas mass in the ICM is also highly correlated with the luminosity from ellipticals and lenticulars present in the cluster. The total mass in the hot-gas component of the ICM ranges from 2×10^{13} to 5.2×10^{14} solar masses within a 3 Mpc radius: this corresponds very roughly to a gas density of 10^{-3} atoms cm^{-3}. The x-ray emission from galaxy clusters is generally interpreted as due to thermal bremsstrahlung in hot gas (gas temperature within 10^7–10^8 K): the observations of the temperature profiles of the hot gas are consistent with the gas itself being in hydrostatic equilibrium, i.e. the gas pressure is balanced by the gravitational force generated by the mass distribution in the cluster. Poor clusters have low central density, low gas mass and low temperature, whereas rich clusters have high central density, high gas mass and high temperature.

The hot emitting gas is enriched with heavy elements: x-ray satellite observations done in the late 1970s revealed the presence of heavy-element emission lines in the x-ray emission associated with clusters. The inferred iron abundance of the ICM seems to have an universal value, i.e. about 0.35 of the solar iron abundance. The detection of the iron lines in the x-ray spectra has shown that the gas is enriched in metals and has been processed, at least in part, into the stellar content of cluster galaxies. The general view is that the heavy elements in the ICM come from galaxies (mainly ellipticals and lenticulars) which eject gas through gas winds which are powered by supernova explosions. In fact the iron masses detected in the ICM are correlated with the luminosity of cluster early-type galaxies. It is interesting to compare the iron yield needed to reproduce the typical observed iron mass over stellar mass ratio in clusters. For a typical cluster, the value turns out to be 5×10^{-3} which is 5 times larger than that measured for the Milky Way galaxy: the conclusion is that one cannot account for the iron mass in the ICM using standard iron mass yield, i.e. that of our Galaxy. Astronomers are led to believe that there was a high supernova activity in cluster galaxies in the past, either a much higher past average SNI rate as compared with the present value observed in ellipticals (at least a factor 10) or a high SNII rate (as generated for istance by a flat initial mass function).

Chemical evolution models, which makes use of bimodal star formation or a higher SNII rate, are able to predict the iron masses (typically of the order of 10^{12} solar masses) in the ICM, but the total ejected masses of gas are always an order of magnitude smaller than the observed ones. This would imply that the bulk of gas observed in the hot x-ray emitting component of the ICM has a primordial origin, i.e. it is pristine material produced during the big bang and was never used to form stars. The agreement between the prediction of the chemical evolution model for early-type galaxies and the observed heavy element content of the ICM is based on the assumption that there had been a complete mixing of the galactic heavy-element-enriched gas with the unprocessed ICM gas on a time scale shorter than the age of the universe.

The recent discovery of massive compact halo objects (MACHOs) and the estimate of their total mass fraction in our galaxy halo may give an alternative explanation for the origin of the hot gas in the ICM. The latest observations indicate that MACHOs may constitute 30–80% of the total galactic halo mass, and, if one assumes that they are common components of all cluster galaxy halos and they are the remnants of an early population of stars that also lost 30% of their initial mass as gas to the ICM, then this mass loss from the stellar progenitors of MACHOs is potentially a very significant source of gas in groups and clusters (see also WIMPS AND MACHOS).

Distribution of the hot diffuse gas

The hot diffuse component of the ICM peaks at the center of the cluster and falls off with distance from the center, and the x-ray emission can be traced out to a distance of 3 Mpc. Recent observations carried out with the latest generation of x-ray satellites indicate that the hot gas in the ICM traces the hierarchical distribution of dark matter in clusters. Recent observations for the nearby Fornax cluster produced a gas density map and the temperature profile of the hot gas over an area of 0.5 square degrees, centered on the galaxy NGC 1399. Using this gas density map and the temperature profile in the hydrostatic equilibrium equation, the mass distribution is computed and the result shows the presence of a more concentrated dark matter distribution associated with the galaxy and a shallower mass distribution at larger radii associated with the cluster. Similar evidence is also found for the Virgo cluster. Such observations are crucial to establish the clustering properties of the dark matter, which are strongly dependent on its intrinsic nature.

Additional components of the ICM

The sum of the masses in cluster galaxies, stellar diffuse plus hot gas ICM components in clusters, can account for up to 30% of the gravitational mass needed to keep any clusters bound. Therefore an additional '*unseen*' dark component is present in the ICM. Possible candidates for dark matter constituents are MACHO-like objects and remnants of massive stars, such as black holes, neutron stars or cool white dwarfs, but, particularly in the case of the dark component of the ICM, elementary particles or non-baryonic matter are important as dark matter candidates. In clusters of galaxies the ratio between the so-called 'baryonic mass' and total mass is near the limit imposed by nucleosynthesis constraints, based on the relative abundances of light elements such as deuterium, helium and lithium observed in our universe, and a cosmological model with $\Omega_0 = 0.2$. Therefore any additional dark components in clusters must be in some sort of non-baryonic form.

Future developments

The new x-ray observations made with the x-ray ASCA satellite are indeed giving astronomers new insight into the properties of the hot-gas component of the ICM; the determination of the number counts of the stellar component of the ICM via large-format CCD images and observations with the new advanced camera on the Hubble Space Telescope will give the welcome opportunity to determine the local mass-over-light ratio of the ICM itself. These two complementary lines of work will help in understanding the mechanism which led to the formation of clusters, and therefore to galaxy and star formation within the cluster itself. The use of the most accurate temperature profiles and gas density distribution maps at high resolution will represent a powerful tool to determine the accurate cluster mass spectrum which is crucial for its implications for cosmological models and the determination of the average mass density of the universe.

Io: Plasma Torus

The discovery of the four largest moons of Jupiter (Io, EUROPA, GANYMEDE and CALLISTO) by GALILEO GALILEI in 1610 was crucial to the rejection of the then prevalent theory that the Earth was at the center of the universe. In the following 350 years, several additional small satellites of Jupiter were discovered (see JUPITER: SATELLITES) but relatively little was learnt about the physical properties of what are now called the Galilean satellites and nothing was known of their interaction with Jupiter and its magnetic field. A turning point occurred in 1964 when E K Bigg showed that radio emissions from Jupiter at decametric wavelengths (previously discovered by Franklin and Burke in 1950) were modulated by the orbital position of the innermost Galilean satellite, Io. The presence of radio emissions indicated that Jupiter had a significant magnetic field and the modulation by Io suggested a complex interaction between the magnetic field and the Galilean satellite (see JUPITER: MAGNETOSPHERE, MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS).

The next important discovery was made by R A Brown in 1972 who detected optical emission from a neutral sodium gas cloud surrounding Io and accompanying it in its orbit about Jupiter. Sodium atoms have two strong lines at visible wavelengths (589.0 nm and 589.6 nm) which are excited by a resonance scattering mechanism. The Sun provides the light source in this case and the sodium neutrals scatter any light at the emission wavelengths they receive in their rest frame. Although the light source comes from only one direction (the Sun), the emission is essentially isotropic. At the rest wavelengths of neutral sodium emission, the luminosity of the Sun is actually rather low because of deep FRAUNHOFER LINES. However, Io has an orbital velocity of 17.4 km s^{-1} about Jupiter. The neutral sodium cloud accompanying Io in its orbit therefore sees the solar illumination Doppler shifted by up to about 0.02 nm (the Doppler shift being greatest when Io is at its greatest elongation from Jupiter as seen from the Sun). This is sufficient to provide a 10-fold modulation of the brightness of the sodium gas cloud surrounding Io depending upon the orbital phase of the satellite.

The neutral sodium cloud is a further product of the interaction between Io and Jupiter's magnetic field. Io orbits at a radial distance of 5.91 Jupiter radii (R_J) where 1 R_J is equivalent to 7.138×10^4 km. Jupiter's magnetic field, which defines the rotation rate of Jupiter, has an angular velocity of 870.536° day^{-1}. The magnetic field at Io's orbit is completely dominated by Jupiter (i.e. there is no influence on the magnetic field strength from the solar wind interaction—this only becomes important at distances greater than about 20 R_J from the planet). Io itself may have a small intrinsic magnetic field but this remains unproven. The magnetic field lines of Jupiter co-rotate with the rotation of the planet. Therefore, at Io's orbit, the field lines have a velocity of 74.2 km s^{-1} and have a velocity with respect to Io of 56.8 km s^{-1}. Ions produced in Jupiter's magnetic field are trapped and co-rotate with the magnetic field (this is a consequence of Faraday's law). Hence, magnetospheric ions have a high relative velocity with respect to Io. Ions which impact the surface and/or atmosphere of the satellite have considerable energy which is used to eject fresh neutrals from Io. This sputtering process, with some minor modifications, is still thought to be the principal mechanism by which material is removed from Io 25 years after it was first suggested by Matson *et al*. Recently, strong evidence has been presented suggesting that this sputtering process might be supplemented by direct removal of ions (produced by photoionization of SO_2 for example) from Io's atmosphere by the co-rotating magnetic field.

The flyby of Io by the VOYAGER 1 spacecraft in 1979 provided a huge leap in our knowledge of the Jupiter system. The main result was the discovery of active volcanism (see IO: VOLCANISM AND GEOPHYSICS) which had been predicted by Peale, Cassen and Reynolds in an article in *Nature* published just five days before the flyby. Volcanism is a possible consequence of tidal forces acting on Io produced by an orbital resonance between Io, Europa and Ganymede. The surface of Io was observed to be almost craterless, indicating rapid resurfacing of the satellite resulting from the volcanism. The estimated resurfacing rate is around 0.1 mm per year. The remarkable colors on the surface indicated a predominance of sulfur and the satellite was shown to have a tenuous SO_2 atmosphere. In addition, the plasma in Jupiter's magnetosphere near the orbit of Io was shown to be dominated by sulfur and oxygen ions. The latter provided remarkable confirmation of the ground-based detection of emission from S^+ ions in Jupiter's magnetosphere made by Kupo *et al* in 1975. This observation was controversial at the time because it appeared to contradict measurements made by the PIONEER 10 spacecraft which seemed to indicate a dense plasma dominated by protons. Ground-based observers prior to the Voyager 1 flyby consistently measured S^+ emission appearing to come from a ring about Jupiter centered roughly on the orbit of Io. Electron densities could be determined by measuring the ratio of an S^+ emission doublet at (671.6 nm and 673.1 nm) produced by collisional excitation. Values between 1000 and 10 000 cm^{-3} were consistently recorded—much lower than densities derived from Pioneer 10 measurements. Just prior to the Voyager 1 flyby, Pilcher and Morgan detected emission from O^+ through its collisionally excited doublet at a wavelength of 372.7 nm.

The Voyager results completely vindicated the results from ground-based observations and gave a clear picture of the plasma environment near Io's orbit. Plasma in Jupiter's magnetosphere sputters material

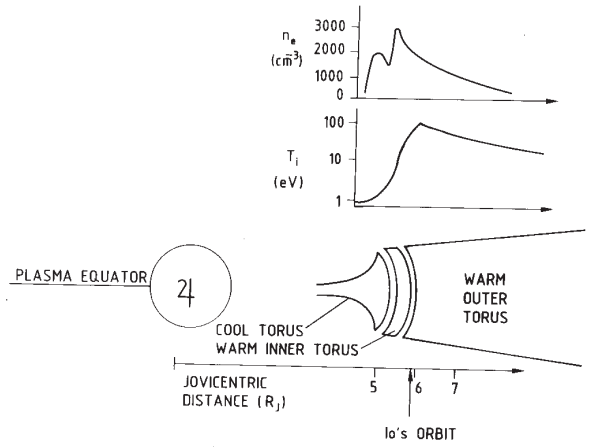

Figure 1. Schematic diagram showing a section through the torus. The 'plasma equator' indicates the equilibrium position for ions in the torus. This plane is tilted by about 7° with respect to the rotation equator. The variations of ion density and temperature in the torus with Jovicentric distance are shown in the form of plots. The density peaks just inside Io's orbit in a region referred to as the 'warm inner torus' (or sometimes 'the ribbon'). The temperature peaks just outside Io's orbit and decreases radially outwards as the plasma expands into the middle magnetosphere. Inside the warm inner torus, the plasma is cold. The regions have been widely separated in the diagram for emphasis.

from the surface and/or atmosphere of Io, producing a series of neutral clouds. Neutral sodium is the most easily detected from ground-based observation because it is a remarkably efficient scatterer of sunlight. However, it is only a trace element, making up around 5% of the neutral clouds. Sulfur and oxygen neutrals actually dominate the composition. Oxygen atoms have been detected from ground-based observations at 630.0 nm. Electrons in Jupiter's magnetosphere interact with the neutrals to produce ions by electron impact ionization. The ions are then picked up by Jupiter's co-rotating magnetic field. The ions are thus swept into a ring about Jupiter centered roughly on Io's orbit. The ions diffuse both inwards and outwards from this ring to fill a torus-shaped volume in space which is called the Io plasma torus or 'IPT'.

The density, temperature and composition of the IPT vary strongly with the radial distance from Jupiter. Figure 1 shows a schematic diagram of a section through the torus.

Inside Io's orbit the plasma is cool and the composition is dominated by singly ionized species (mostly S^+ and O^+). The electron and ion temperatures, although not in equilibrium, rise rapidly between 5.4 R_J and 6.0 R_J. The higher-energy electrons give rise to a more highly ionized plasma and S^{2+} becomes the most numerous sulfur ion around 5.8 R_J. The electron temperature continues to rise outside Io's orbit and more highly ionized species are seen as one moves towards the middle magnetosphere of Jupiter. The ion temperature, however, decreases due in part to the expansion of the plasma into the middle magnetosphere. The electron density reaches a maximum of around 3000 cm^{-3} at around 5.7 R_J—just inside the orbit of Io. The estimated composition at 5.9 R_J (at Io's orbit) is estimated to be 14% S^+, 48% O^+, 19% S^{2+}, 2% O^{2+}, 2% S^{3+}, 2% Na^+, <2% SO^+_2. A 10% mixing ratio of protons is usually assumed but this is uncertain. The estimated mass of the IPT is around 2–10^6 tonne.

The Voyager spacecraft provided only a snapshot of the conditions in the IPT during its flyby. Observations of the IPT using ground-based telescopes (e.g. the European Southern Observatory) and Earth-orbiting observatories (e.g. Hubble Space Telescope, International Ultraviolet Explorer, Extreme Ultraviolet Explorer, Infrared Space Observatory) have become the main tools in the investigation of the IPT since they provide both a synoptic view of the IPT and can be used to investigate the time variability of the IPT. All observable emissions are produced by collisional excitation and therefore the observed intensity in any emission line is proportional to the product of the electron density and the ion density integrated along the line of sight through the toroidal volume. Because Earth-based observers view the torus

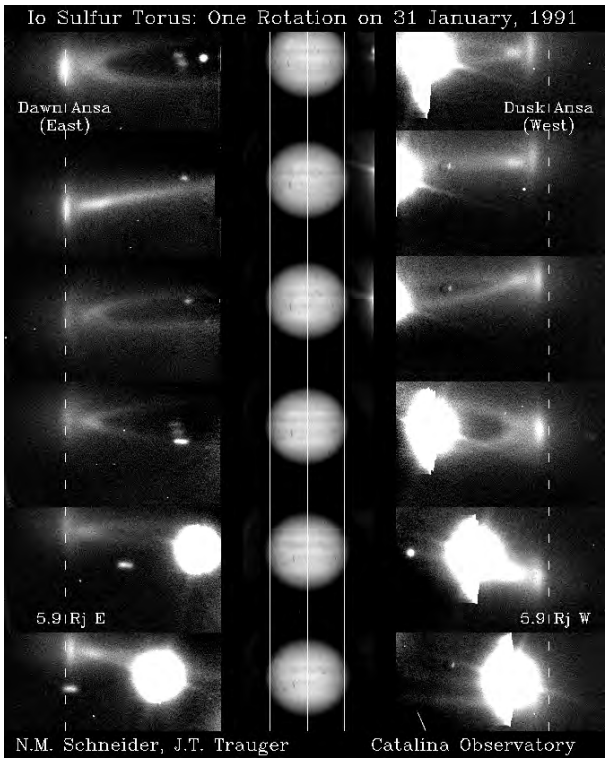

Figure 2. A time-series of ground-based observations of the Io plasma torus. Jupiter is seen in the center of the frame. Jupiter rotates in 9.925 h. The Io torus oscillates over this time scale because the magnetic axis of Jupiter is tilted by 9.8° with respect to its spin axis. The ionized sulfur emission seen here also shows an east (left)–west (right) brightness asymmetry. Image courtesy of N M Schneider (University of Colorado) and J T Trauger (JPL).

roughly edge-on, the maximum emission is seen at the ansae (outer edges) of the IPT around 5.7 R_J from Jupiter in projection (see figure 2) and decreases rapidly as the radial distance decreases. Most of our knowledge stems from observations of the ansae of the IPT over a rather limited radial distance from Jupiter (roughly 5.0–6.5 R_J). The integrated emission from the IPT is around 4×10^{12} W with the strongest emissions being in the extreme ultraviolet. The 68.5 nm emission of S^{2+} is responsible for 5% of the emission from the IPT alone.

Figure 2 shows how the IPT appears to wobble in a Jupiter-centered reference frame. Jupiter's magnetic dipole is tilted by 9.8° with respect to the rotation axis. The equilibrium position for ions in a dipole magnetic field is the magnetic equator (where the magnetic mirror force becomes zero). However, Jupiter is rotating with high angular velocity and thus the centrifugal force on the ions has to be taken into account. As a result, the equilibrium position for the ions is at the so-called centrifugal equator which is between the rotational equator and the magnetic equator. The centrifugal equator is tilted by about 7° with respect to the rotational equator. In a reference frame connected to Jupiter's rotation axis, the IPT therefore appears to wobble with the ansae oscillating up and down with an amplitude of about 1.4 R_J (peak to peak).

Another feature of figure 2 is that the IPT on the west of Jupiter (right) appears to be brighter than on the east (left). This feature was first recognized in Voyager data and is believed to be caused by the existence of an electric field which shifts the IPT slightly towards the east as seen from the Earth (Barbosa and Kivelson 1983). IPT ions in the east are therefore slightly further away from Jupiter than their counterparts in the west. Being further away in a dipole system, the ions are less confined and therefore less dense. Collisional excitation is strongly proportional to density and thus the east appears slightly fainter.

The IPT is highly variable on several different time scales. A variability is seen in the brightness of the torus with a period equal to Jupiter's rotation period (System III). The brightness modulation is anti-correlated with the ion temperature (Schneider and Trauger 1995). The mechanism producing this phenomenon is at present unknown. A second variation with a period roughly 3% longer than System III (sometimes referred to as System IV) is also evident and may be the result of long-lived density waves in the IPT (Roesler *et al* 1984). The torus is also variable on long time scales and can vary in brightness from year to year by up to a factor of 4. There is also some evidence that the flow past Io modifies the plasma parameters so that the brightness downstream of Io is slightly enhanced.

New observations of Jupiter, its satellites and environs have been made by Cassini, Galileo, the Hubble Space Telescope, the Chandra X-ray Observatory and Earth-based radio and optical telescopes during the CASSINI spacecraft's flyby. The GALILEO spacecraft has been in orbit around Jupiter since December 1995 while Cassini observed Jupiter from 1 October 2000 to 31 March 31 2001. Cassini made its closest approach on 30 December 2000, at a distance of about 9.7 million kilometers (6 million miles). Data from the flyby observations show that Io leaves a magnetic footprint on Jupiter's upper atmosphere which appears as a spot of ultraviolet emission that remains fixed underneath Io as Jupiter rotates. The specific physical mechanisms responsible for generating these emissions are not well understood, but in general the spot seems to arise because of an electromagnetic interaction between Jupiter's magnetic field and the plasma surrounding Io, driving currents of around 1 million amperes down through Jupiter's ionosphere. Io's magnetic footprint extends well beyond the immediate vicinity of Io's flux–tube interaction with Jupiter, and much farther than predicted theoretically; the emission persists for several hours downstream.

The Cassini spacecraft has also discovered a fast (greater than 10^3 kms^{-1}) and hot magnetospheric neutral wind extending more than 0.5 au from Jupiter, and the presence of energetic neutral atoms (both hot and cold) that have been accelerated by the electric field in the solar wind. It is suggested that these atoms originate in volcanic gases from Io, undergo significant evolution through various electromagnetic interactions, escape Jupiter's magnetosphere and then populate the environment around the planet. Thus a 'nebula' is created that extends outwards over hundreds of Jovian radii.

Io: Volcanism and Geophysics

Io is the innermost of the four large Galilean satellites of Jupiter discovered by Galileo Galilei in 1610. Io's mean radius (1821 km) and bulk density (3.53 g cm^{-3}) are comparable with those of the MOON. However, long before the VOYAGER spacecraft encounters, it was apparent from Earth-based observations that Io is very different from the Moon: it has an unusual color and anomalous thermal properties, and it is surrounded by immense clouds of ions and neutral atoms. These observations were much better understood following the discovery of active volcanic plumes and hot spots on Io during the Voyager 1 spacecraft encounter in 1979. The volcanism is driven by tidal heating, from periodic deformation of Io's shape as it orbits massive JUPITER.

Many Voyager-era investigators thought that Io's active volcanism was dominated by sulfurous eruptions rather than the silicate volcanism seen in the inner solar system. More recent observations by Earth-based telescopes and the GALILEO MISSION (1995–1998+) have shown that the volcanism on Io is dominated by high-temperature eruptions of silicate lava.

Gravity measurements from tracking of the Galileo spacecraft indicate that Io has a large iron or iron–iron sulfide core, constituting up to 20% of the satellite's mass. The bulk density of Io, its rugged topography and models of satellite origin suggest that the bulk composition of the crust and mantle is silicate. However, the surface composition has been greatly altered by volcanic outgassing. Sulfur dioxide (SO_2) has been positively identified both as a gas and as a surface frost. Elemental sulfur is considered a likely surface component on the basis of (1) the similarity of Io's ultraviolet through near-infrared spectral reflectance to that of powdered sulfur and (2) the detection of sulfur ions in IO'S PLASMA TORUS. The detections of clouds of Na and K around Io indicate that these elements must be present on the surface in some form.

Tidal heating mechanisms and internal structure

The importance of tidal heating in powering the enhanced heat flow and active volcanism of Io is widely accepted. All plausible non-tidal heat sources are about 2 orders of magnitude less energetic than the power output of Io (at least 10^{14} W). Accretional heating can supply, at most, half the gravitational potential energy of Io; the power output, averaged over 4.5 billion years, is 5×10^{11} W. However, the accretional heat was probably removed by conduction or convection very early in Io's history. Core formation can supply only a fraction of the maximum accretional energy, and it also is short lived. Radiogenic heating is a continuous process and is estimated to supply 5×10^{11} W. Heating of the surface by an electrical current running between Io and Jupiter's ionosphere provides a maximum power of 2×10^{11} W, but an ionosphere is likely to divert most of the current around Io.

The basic tidal heating mechanism involves deformation of Io into a triaxial ellipsoid by Jupiter's gravitational field. Because Io's orbit is eccentric, the satellite undergoes a periodic deformation. The dissipation also decreases Io's orbital eccentricity, which is forced to remain non-zero by the orbital resonance between Io and EUROPA. The total rate of tidal dissipation within Io depends on the internal structure and material properties of both Io and Jupiter. In particular, the transfer of orbital energy from Jupiter to Io is a consequence of the bulge raised on Jupiter by Io, and the rate of such transfer depends on Jupiter's dissipation factor, but this value is poorly known.

The mechanism of heat dissipation is intimately tied to Io's internal structure. An early model, with 'runaway' melting of the interior and tidal energy dissipated within a thin, elastic lithosphere, now seems unlikely. Dissipation of all the tidal energy within the lithosphere requires that it be 8–18 km thick, and such a thin lithosphere is inconsistent with the presence of mountains more than 10 km high (see below). The model may be modified by invoking a thicker lithosphere and heat transfer by volcanism rather than conduction, perhaps overlying crystal-rich magma rather than a fully molten interior. However, runaway melting might never have occurred if subsolidus convection removes the heat faster than it is added. Most workers consider Io to be a differentiated body with an iron-rich core, a solid mantle perhaps with an upper partly molten layer, overlain by a thick (30–100 km) lithosphere. Most of the tidal energy is probably dissipated by viscous or viscoelastic deformation below the lithosphere, and most of the heat is transported to the surface by silicate magmas.

Geomorphology

The morphology and surface markings on Io are almost entirely the result of volcanic processes, with the possible exception of the high mountains. Impact craters, the dominant landform on most solid planetary bodies, have not been observed on Io, despite the comet flux concentration by Jupiter's gravity. The lack of impact craters indicates that the surface is very young, and is consistent with estimates of resurfacing by volcanic activity ($\sim$1 cm yr^{-1}). The intense volcanism has resulted in a variety of surface features of three general categories: volcanic centers, mountains and plains (figure 1).

Io is spotted by local dark markings that probably consist of recently erupted silicate lavas and marking active volcanic centers. Where picture resolution and illumination conditions permit discrimination of surface relief, many of these markings are seen to lie within depressions that resemble terrestrial calderas. Calderas have steep, scalloped walls, flat floors and smooth rims; they form by collapse over shallow magma chambers following eruption of volcanic materials. Dark markings may cover all or part of a caldera floor and adjacent regions. The calderas range from about 10 to 200 km in diameter and are as deep as $\sim$2 km. Most calderas are not

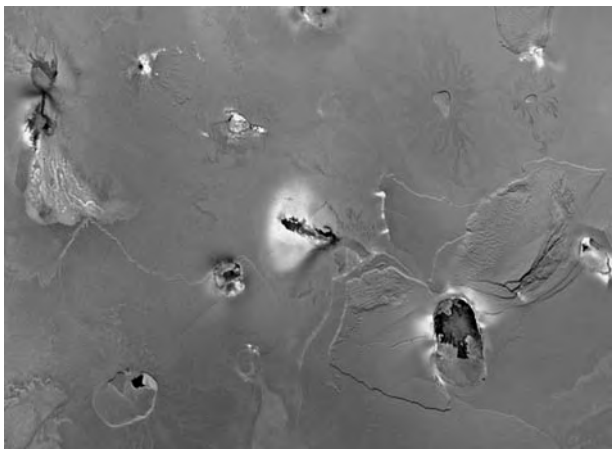

Figure 1. Mosaic of Voyager images of Io at a scale of 1 km/pixel. The landforms of Io include tall mountains, plateaus, calderas and layered plains. There are also color and albedo markings suggestive of lava flows and plume deposits.

associated with an obvious edifice, but some low shield-shaped edifices with summit calderas are present. The steep caldera walls and association with high-temperature hot spots are inconsistent with the concept of a thick sulfur crust. Io's crust is probably composed of silicate rocks, and the sulfurous materials form a relatively thin surface veneer as well as ground fluids at depth.

Elongated sinuous markings like lava flows can be seen in many areas, especially when not confined within a caldera (figures 1 and 2). (The caldera floors may be covered by coalesced flows, so the flow margins are less apparent.) Most dark markings are sources of high-temperature hot spots consistent with ongoing eruptions of silicate lava. Thus, the dark areas are the sites of active volcanic vents, and there are about 100 such active centers on Io. The spectral reflectances of the dark materials are consistent with silicates containing magnesium-rich orthopyroxene, and with varying degrees of sulfurous coatings. Diffuse bright white, yellow and red markings in and around volcanic centers are common and may be the result of sulfurous fumarolic and plume activity.

The second major class of surface feature is mountains, which typically have irregular outlines and rugged surfaces that appear tectonically disrupted. They may be as large as 600 km in basal diameter and 15 km high. The origin of these high mountains is not resolved. They may be degraded volcanoes, exposures of a silicate basement complex or uplifted (and sometimes tilted) crustal blocks. Most workers agree that the mountains must be dominantly silicate rather than sulfur, because sulfur does not have sufficient strength to support the observed relief. Although superposition relations are unclear, the mountains are generally considered to be the oldest materials exposed on Io's surface, but higher-resolution images are required to confirm this hypothesis.

Most of Io's surface is covered by plains with little apparent relief. They have complex ALBEDO and color patterns, and, where relief is discernible, they are often seen to be layered. The plains and their surface patterns may have been formed by a variety of materials and processes, including lava flows, deposition from plumes, condensation of volatiles and possibly pyroclastic flows.

Volcanic plumes

One of the most dramatic phenomena on the surface of Io is the active volcanic plumes. They erupt under conditions of pressure, temperature and gravity very different from those on Earth, and they are probably driven by SO_2 and/or sulfur in which multiple phase changes can occur, so the plume dynamics and thermodynamics are unlike those of terrestrial eruptions. The low gravity and especially the very low atmospheric pressure on Io ($\sim 10^{-9}$ bar) result in plumes up to 10^4 times larger on Io than would be produced by comparable eruptions on Earth (see VOLCANISM IN THE SOLAR SYSTEM).

Nine eruption plumes were observed during the Voyager 1 encounter; eight of these were also observed 4 months later by Voyager 2. Galileo has observed a total of 10 plumes as of mid-1998, four of which appear related to Voyager-era plumes, so there are a total of 15 volcanic centers with observed plumes. Ring-shaped surface deposits suggest that many other plumes have been recently active as well. Many of the plumes, such as that of Prometheus (figure 2), are 50–150 km high, long lived, deposit bright white material (probably SO_2 frost) and are associated with high-temperature hot spots. Prometheus and other plumes show signs of lateral migrations over time of up to 100 km. Pele's plume is very different from Prometheus-type plumes, as it is very faint at visible wavelengths, up to 460 km high and deposits bright red material. The Pele hot spot is also unusual because it maintains an intense high-temperature component at surprisingly constant levels over long periods of time.

The dominant volatiles driving explosive volcanism on Earth, H_2O and CO_2, seem to be highly depleted on Io. Discernible H_2O or carbonate absorption bands are absent, and C has not been detected in Jupiter's magnetosphere near Io (see JUPITER: MAGNETOSPHERE). H has been detected over Io's poles, which may indicate the presence of magmatic H_2O or H_2S. Nevertheless, volatiles such as SO_2 or sulfur are thought to be the major species driving the explosive volcanism.

Surface changes

About 30 large-scale (tens of kilometers) surface changes are obvious from comparison of the Galileo images with those acquired by Voyager in 1979 (figure 2). These include new plume deposits of several colors, bright and dark flows, and caldera-floor materials. There have also been significant surface changes on Io during the Galileo mission, such as a new 400 km diameter dark deposit around Pillan Patera (figure 3). While these surface changes are impressive, the number of large-scale changes observed in the 4 months between the Voyager 1 and Voyager 2 flybys in 1979 suggested that over 17 years the cumulative

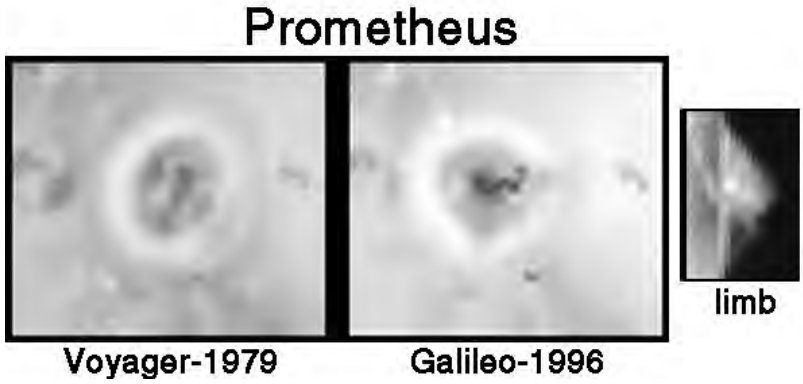

Figure 2. Three views of the active plume Prometheus. The left image shows the Prometheus region as seen by Voyager, and the middle view shows the same region seen by Galileo. There are new dark lava flows and the plume vent has moved about 70 km to the west. The right view shows the plume on the limb, against black sky, as seen by Galileo. Plume's height is 75 km, and bright ring has a diameter of about 300 km.

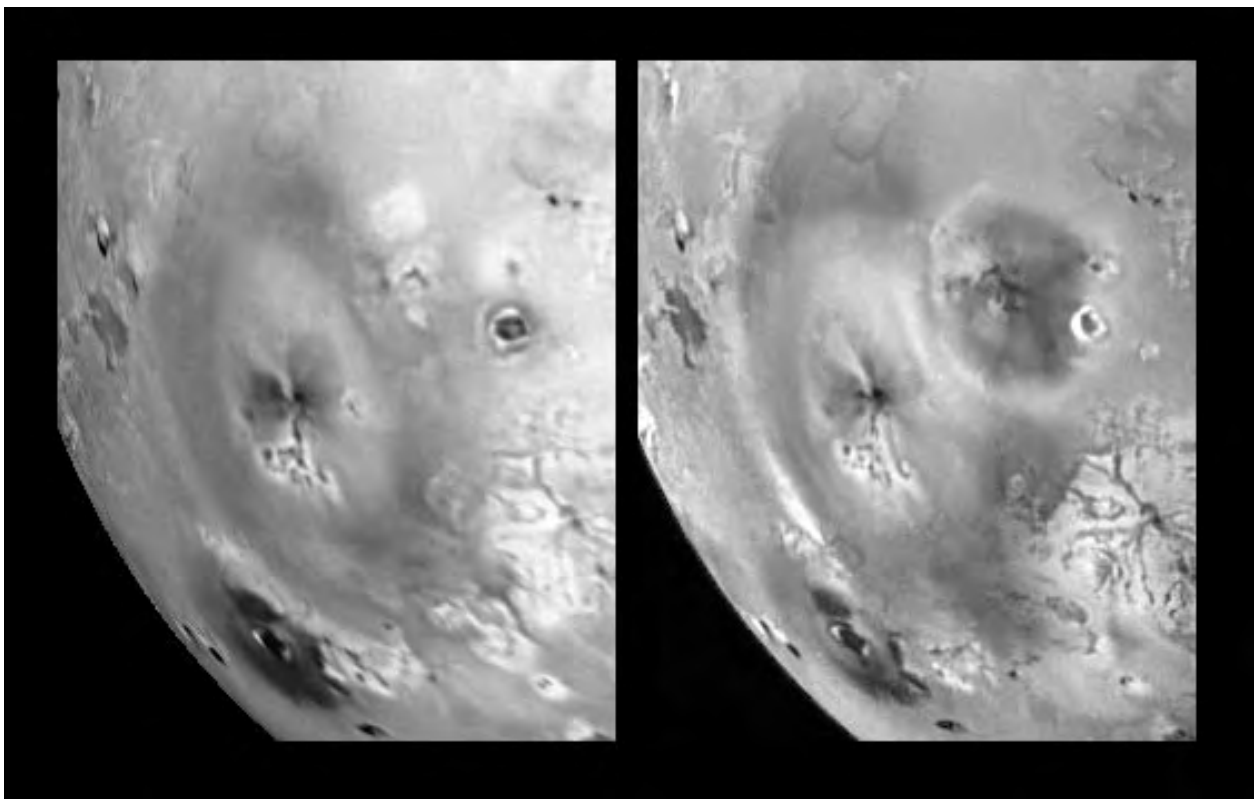

Figure 3. Two views of the Pele and Pillan volcanoes on Io, as seen by Galileo in the spring of 1997 (left) and fall of 1997 (right). The large ring is the fallout deposit of the 460 km high Pele plume. The eruption near Pillan Patera north-east of Pele produced the new dark deposits seen in the right-hand image, with a diameter of 400 km.

changes would have been much more impressive. There are two reasons why this was not actually the case. First, the most widespread plume deposits are ephemeral and seem to fade away within a few years. Second, it appears that a large fraction of the volcanic activity is confined to repeated resurfacing of dark calderas and flow fields that cover only a few per cent of Io's surface.

Hot spots

Evidence for hot spots or thermal anomalies on Io was acquired years before the Voyager encounters, but it was not understood. Thermal infrared observations

Figure 4. Image of Io in eclipse (when Io is in Jupiter's shadow). Small bright spots are high-temperature hot spots. The two brightest spots are due to Pele and Pillan (see figure 3). Pillan produced a very high-temperature hot spot, with lava temperatures exceeding 1700 K, probably because of the eruption of ultramafic lava from Io's mantle. Diffuse glows from electronic excitation of gases highlight Io's limb and active plumes.

had revealed two curious relations. First, when Io is eclipsed by Jupiter (figure 4), its temperature falls as expected for a surface with low thermal inertia, but its minimum temperature is too high. Second, the infrared brightness temperature of Io is significantly higher at shorter wavelengths. After the Voyager 1 encounter and the discovery of active volcanism, these observations were understood as being due to hot spots with temperatures well above 150 K, the peak temperature of the surface if heated only by the distant Sun. More than 50 hot spots have detected by Voyager, Galileo and telescopic observers. Voyager could not detect small areas at temperatures higher than ∼650 K because of limitations in sensitivity and wavelength coverage. Ground-based telescopic observers and Galileo have detected much higher temperatures, consistent with silicate volcanism.

Observations by Galileo have confirmed that high-temperature hot spots are ubiquitous on Io. There are more than 40 volcanic centers that reveal temperatures well above those expected from sulfur volcanism. Perhaps most surprising, however, has been the discovery than at least a dozen of these centers are erupting lavas with temperatures exceeding 1500 K, the peak temperature of basaltic lavas erupting on Earth. The most likely explanation is that these lavas are ultramafic (magnesium-rich) silicates.

The current eruption of ultramafic lavas raises questions about the composition of Io's crust. The intense volcanic activity, if it has persisted for at least a few per cent of geological time, should have strongly differentiated the silicates in Io. This differentiation, in the absence of remixing, should produce a ∼50 km thick, low-density crust rich in the lighter elements common in silicate rocks such as sodium, potassium, silica and aluminum. However, the high-temperature lavas suggest that dense melts from the magnesium-rich mantle are reaching the surface, so vigorous mixing between the mantle and crust may produce a crust with a mafic composition.

The best estimate of Io's global hot-spot heat flow is 2.5 W m^{-2}, and Io's total heat flow may be twice this value owing to conducted heat from recently emplaced lava flows. Therefore, the total energy loss from Io is probably from 2.5 to 5.0 W m^{-2}, orders of magnitude greater than the average heat loss from Earth (0.08 W m^{-2}) or from the Moon (0.02 W m^{-2}). The maximum energy flow theoretically possible from tidal heating is 0.8 W m^{-2} if steady state over the age of the solar system. Since Io's current heat flow clearly exceeds this limit and is emanating from many separate volcanic centers, it seems likely that the rate of tidal dissipation and/or heat flow has varied over time.

Global distribution of volcanism

Active and inactive volcanic centers appear to be almost uniformly distributed over Io, but several types of volcanic activity are non-uniform. The active plumes clearly prefer the equatorial region, with 14 out of 15 erupting from within 30° of the equator. The persistently active hot spots (which must release the most heat) are also concentrated in the equatorial region. A field of bright vents seen in eclipse occurs over the sub-Jovian region, and a region of diffuse glow seen in eclipse at low resolution, suggests that a similar field may exist over the anti-Jovian region. The region of Io from longitude 240° to 360° has distinctive color and albedo patterns and the plumes in this region display a greater range of characteristics than plumes at other longitudes.

The distribution of volcanism over Io's surface can be expected to reveal something about the nature of heating within the interior. Because of the intense tidal heating and the apparently high temperatures in Io's interior, convection should be the main internal mode of heat transfer. If tidal heating is predominantly in a partially molten layer (asthenosphere) of order 100 km thick, convection should occur globally in the asthenosphere with centers of upwelling and downwelling separated by a few hundred kilometers. Modeling indicates that the heat flow should be highest in the equatorial regions. Thus this model nicely explains the presence of active or recently active volcanic centers peppering the surface at several hundred kilometer intervals, and with an equatorial concentration of more energetic hot spots. The distribution of active plumes seems to follow the distribution of especially energetic volcanic centers, although plumes have not (yet) been seen at many of these centers.

The major current exception to this uniform longitudinal pattern of heat flow is Loki Patera, an especially large dark-floored caldera which alone accounts for about a quarter of Io's heat loss. The heat being radiated from Loki is an order of magnitude larger than the heat loss from all the Earth's currently active hot spots. Tidal heating in the deep mantle would result in larger-scale convection perhaps with a relatively small number of mantle plumes spaced widely apart and carrying most of the deeply generated heat. Perhaps this can explain the Loki anomaly.

Future exploration

Many important questions about Io remain unanswered. The Galileo spacecraft reached Jupiter and made a close flyby of Io in 1995, but a tape recorder anomaly precluded the acquisition of high-resolution images or spectra of Io. With the extended mission now in progress, the plan is to return to Io in late 1999. There will be two close flybys of Io, one a near-equatorial pass providing a close look at volcanoes such as Pele and Pillan, and the second a pass under the south pole to determine whether Io has a self-sustained magnetic field. Other key issues that will be addressed are (1) emplacement mechanisms and compositions of erupting lavas, (2) composition of the crust, (3) origins of the large mountains and other landforms, (4) dynamics of the plumes and (5) polar volatile compositions.

Ion

An atom that has a net electrical charge because it has lost, or gained, one or more electrons relative to the normal complement possessed by a neutral atom. The number of electrons in an ordinary, neutral, atom is the same as the number of positively charged protons in its nucleus. Compared to a neutral atom, a positive ion has fewer electrons (and a net positive charge) and a negative ion has more (and a net negative charge). The term 'ion' also applies to molecules and other groupings of atoms with a net electrical charge.

See also: atom, electron, ionization, molecule, proton.

Ionization

The process whereby atoms lose one or more electrons to become positively charged ions. Ionization will occur if an atom absorbs a sufficiently energetic photon or if it suffers a sufficiently violent collision.

The minimum amount of energy needed to remove an electron to infinity from the ground state of a given atom is called the ionization potential, or ionization energy. For a hydrogen atom, with its single electron in the ground state (the lowest energy level of the atom), the ionization potential is 13.6 electronvolts (eV). If the electron is in a higher (excited) level, less energy is needed to remove it from the atom. In general, the ionization potential (IP) for an electron in excitation level n ($n = 1$ for the ground level, 2 for the first excited level, and so on) of a hydrogen atom is given by $\mathrm{IP} = 13.6/n^2$ eV. Thus, for example, the energy required to remove an electron from the first excited level $(n = 2) = 13.6/2^2 = 13.6/4 = 3.4$ eV. Where an atom has two or more electrons, the ionization potential for the second and subsequent electrons is greater than for the first electron. For example, the ionization potentials for the first and second electrons in a helium atom are 24.6 eV and 54.4 eV respectively. Where the energy (E) absorbed by an electron exceeds the ionization potential (IP), the kinetic energy of the escaping electron is given by $E - \mathrm{IP}$.

An atom that has lost one electron is identified by the roman numeral II (the neutral atom, by I) or by the superscript +. For example, neutral hydrogen is denoted by HI and ionized hydrogen by HII or H^+. Doubly ionized helium (helium that has lost both electrons) would be denoted by He III or He^{++}. In many astrophysical situations, for example, in very high-temperature gases, very high ionization stages (i.e. atoms that have lost many electrons) are encountered, and the roman convention is normally used; for example, Fe XVI represents an iron atom that has been stripped of 15 out of its total complement of 26 electrons. Ions that retain at least one bound electron can absorb or emit radiation, so producing spectral lines (emission and absorption lines) that differ in wavelength from those produced by neutral atoms. Photons are also emitted when an ion captures, or recaptures, an electron (this process being called 'recombination').

Ionized gases are encountered in a wide variety of astrophysical situations; for example, in the interiors and atmospheres of stars, in luminous nebulae (glowing clouds that contain substantial quantities of ionized hydrogen and which, for that reason, are otherwise known as HII regions), or in high-temperature intergalactic gas.

Irish Astronomy

This account of national astronomy in Ireland is given under four categories: (1) national astronomical observatories, (2) university and college departmental astronomy, (3) private astronomical observatories and individuals and (4) astronomical societies and groups. A short history of each establishment is followed by a report on its current status together with present research activities. The article is partly composed from published literature.

National astronomical observatories

Dunsink Observatory

DUNSINK OBSERVATORY, the observatory of Trinity College Dublin, was founded in 1783. It was designed by the architect Graham Moyers according to principles laid down by Henry Ussher. Ussher was the first director of the new observatory, and he held office until his death in May 1790.

Initial work at the Observatory included stellar and planetary positional astronomy using transit instruments by Jesse Ramsden and astronomical regulators by Arnold and Crosthwaite. Stellar positional astronomy was begun in Dublin by Henry Ussher on 1 January 1788. Ussher maintained a weather record from July 1786 to May 1790, and it was he who encouraged and guided the young (later Admiral Sir) Francis Beaufort.

John Brinkley succeeded Ussher as Andrews' Professor in December 1790, becoming Royal Astronomer in 1792. The problem of measuring the distances of the stars occupied much of Brinkley's time. The method used was to measure the apparent motion of nearby stars against the more distant stellar background utilizing the different viewing positions afforded by the annual motion of the Earth in its orbit around the Sun.

Brinkley was followed in 1827 by Sir William Rowan Hamilton, then 21 yr of age, who held the post of Director until 1865. Internationally respected as a mathematical genius, Hamilton invented quaternions, an algebraic system with similarities to vector analysis. He scratched the following set of equations on a stone of Broome (Brougham) Bridge near Dublin on 16 October 1843:

$$\mathrm{i}^2 = \mathrm{j}^2 = \mathrm{k}^2 = \mathrm{ijk} = -1.$$

Various cyclic properties resulting from these equations also hold true and so with four pure numbers a quaternion may be formed as follows:

$$q = a + b\mathrm{i} + c\mathrm{j} + d\mathrm{k}.$$

A scalar is simply a quarternion with $b = c = d = 0$, while a vector is one with $a = 0$. Hamilton also made significant contributions in optics and mechanics, and predicted conical refraction.

Robert Stawell Ball headed the Observatory from 1874 until 1892, his main contribution being in the theory of screws dealing with the movements of a rigid body in three dimensions.

Several later holders of the office of Director of Dunsink Observatory were accomplished mathematicians: Charles Jasper Joly, Edmund Taylor Whittaker and Henry Crozier Plummer. Joly (1897–1906) wrote many articles on quaternions and edited Hamilton's *Elements of Quaternions*. He also compiled a zodiacal catalogue, that is a catalogue of stars lying in the ecliptic or apparent path of the Sun through the heavens. Whittaker (1906–12) wrote texts on *Modern Analysis* and *Analytical Dynamics*, while the future Prime Minister and President of Ireland, Eamon de Valera, attended lectures given by Whittaker. Plummer (1912–21) commenced the study of variable stars and star clusters, as well as writing the text *An Introductory Treatise on Dynamical Astronomy*.

Following Plummer, Charles Martin was appointed acting Director in 1921 and occupied the position until 1936. Dunsink Observatory then fell into abeyance, closing in 1937. However, in 1943, de Valera obtained government approval for the establishment of the School of Cosmic Physics in the recently constituted Dublin Institute for Advanced Studies (DIAS), and by 1947 approval for the School was passed. By this time, Dunsink Observatory had been acquired by the State and, reopening in 1947 under the direction of Hermann Alexander Brück, became the astronomy section of the School of Cosmic Physics.

Soon after reopening, a proposal was put forward by Eric Mervyn Lindsay (see below) to establish a large telescope in the southern hemisphere, the Armagh–Dunsink–Harvard (ADH) Telescope—a 36 in Baker–Schmidt later equipped with a 33 in diameter objective prism. Solar studies were also commenced at Dunsink with the erection of a vertical CASSEGRAIN TELESCOPE and concave grating spectrograph. Measurements of the solar ultraviolet spectrum between 310 and 360 nm were incorporated in the second revision of Rowland's Preliminary Table. Stellar photoelectric photometry studies were initiated with the 28 in reflector in pulse-counting mode. A study of the interstellar absorption band at 443 nm was also undertaken. The scintillation, or *twinkling*, of the stars was also the subject of intensive study at this time.

Brück resigned in 1957 to take up the posts of Astronomer Royal for Scotland and Professor of Astronomy in the University of Edinburgh. Mervyn Archdall Ellison succeeded to the Dunsink post in 1958, undertaking solar flare observations with Dunsink then becoming a world data center for such studies.

Following Ellison's untimely death in 1963, Patrick Arthur Wayman was appointed Director in 1964. Investigations of the southern sky included photometry of Magellanic Cloud cepheids. Solar system and extragalactic studies also became important branches of research with the appointment of Tao Kiang to the staff. Kiang studied ancient Chinese records of Comet Halley and the structure of the main asteroid belt lying between Mars and

Jupiter. Wayman retired in 1992 to be replaced by Evert J A Meurs, whose research interests include extragalactic astronomy, particularly active galactic nuclei (AGNs), starburst galaxies and stellar evolution, large-scale structure and clusters of galaxies. The observational material now studied extends beyond the visible light band into higher (x-rays) as well as lower (infrared, radio) energy bands of the electromagnetic spectrum.

The Governing Board of the School of Cosmic Physics recently decided to develop an interactive educational facility, particularly for the general public and school groups, which was opened in December 1997. The subject matter of the principal exhibits is inspired by the Junior Science Curriculum, providing an introduction to the astronomical world and highlighting the role of 'Gravity in the Universe'. There is also the long-established program of Open Nights at the Observatory.

Armagh Observatory

ARMAGH OBSERVATORY was founded in 1790 by Richard Robinson, the Anglican Archbishop of Armagh and Primate of All Ireland, as part of a greater plan for the establishment of a University of Ulster in Armagh. The Rector of the parish of Kildress in Cookstown, Co Tyrone, James Archibald Hamilton, was appointed as the first Astronomer of the new observatory. Astronomical observations began in July 1793 with the timing of a transit of α Ophiuchi using a transit instrument and a clock by Alexander Waugh of Armagh. Meteorological observations commenced in December 1794 and, with the exception of the period 1825–33, have been carried out continuously to the present day.

The early astronomical work consisted of transit observations for rating Thomas Earnshaw's regulator, and determining longitude by lunar observations. An equatorially mounted telescope was commissioned from the firm of J & E Troughton and arrived in December 1795. Hamilton died in 1815 and was succeeded by William Davenport. He concentrated on transit observations and equatorial measurements, but took his life in 1823 in his study.

A successful period in the observatory's history then ensued with the appointment of the highly respected THOMAS ROMNEY ROBINSON. Receiving his early education in Belfast, Robinson, by the age of 12, had printed a book of his own poems, the proceeds from the sale of which enabled him to commence studies at Trinity College Dublin. Robinson acquired a new transit instrument (1827) and mural circle (1831) from Thomas Jones & Son. After 26 yr of arduous labour with these telescopes, he produced a star catalogue entitled *Places of 5,345 Stars Observed at Armagh Observatory between the years 1828 and 1854.* For this catalogue, Robinson was awarded the Royal Medal of the Royal Society.

In 1835, Armagh Observatory acquired a 15 in equatorially mounted, clock-driven REFLECTOR by THOMAS GRUBB of Dublin. This instrument also employed an 18-point suspension system for supporting the primary speculum metal mirror. Robinson had a keen interest in meteorology since his college days and was also the inventor of the Robinson cup-anemometer, a wind-speed measuring instrument, an early version of which, still installed at the Observatory, dates from 1870. Robinson died in 1882 at the age of 89 yr while still in office. He had headed the Observatory for 59 yr, the longest tenure for any observatory director.

Robinson was succeeded by the Danish astronomer, JOHN LOUIS EMIL DREYER, famous historian of astronomy. Soon after arriving in Armagh, Dreyer began soliciting for the construction of a moderately large refractor as a memorial to his predecessor. The outcome was the erection of a 10 in Grubb REFRACTOR in 1885, and with it Dreyer confirmed some of his observations for his *New General Catalogue of Nebulæ and Clusters of Stars* published in 1888, and the two Index Catalogues in 1895 and 1910. Another important text was his *History of the Planetary Systems from Thales to Kepler* (1906). Dreyer also edited the works of that earlier Danish astronomer, TYCHO BRAHE, publishing most of his Tycho work during his tenure at Armagh. Dreyer resigned the directorship of the Observatory in 1916 and moved to Oxford, there to continue his work.

Joseph Alfred Hardcastle, a great-grandson of Sir William Herschel, was appointed director in 1917, but was taken ill while travelling to Armagh and had to stop the journey at his parents' home where he died at the age of 48. The following year, 1918, saw the appointment of the well-known telescope maker William Frederick Archdall Ellison. He held office until 1936. His son, Mervyn (see above), was Director of Dunsink Observatory from 1958 to 1963.

A strong programme of observational astronomy was then initiated by Eric Mervyn Lindsay, Director from 1937 until 1974. Lindsay's vision was to see Armagh Observatory have access to a moderately large telescope at a good observing site. He approached the governments in Belfast and Dublin, as well as HARLOW SHAPLEY of the Harvard College Observatory with the view of setting up a telescope in the southern hemisphere. The result, after much negotiation, was the Armagh–Dunsink–Harvard (ADH) Baker–Schmidt telescope, operating at the Boyden Observatory near Bloemfontein in South Africa from 1950 until 1976. The two nearby galaxies, the Magellanic Clouds, were intensively studied by Armagh astronomers during this period.

Lindsay was also responsible for the establishment of the Armagh Planetarium in the mid-1960s. The Planetarium was officially opened in 1968 with Patrick Moore as the first Director. It was Lindsay who, in 1948, secured a research position in Armagh for the Estonian-born astronomer ERNST JULIUS ÖPIK, who made fundamental contributions to various branches of astronomy, including solar system studies and stellar structure, and remained at Armagh until his retirement in 1981.

Following Eric Lindsay's death in 1974, Öpik became acting Director until the appointment of Martin Jan Hugo de Groot in 1976. For the next two decades the Observatory

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

focused attention on the mechanisms underlying the ejection of mass from hot stars, and the atmospheric and surface activity of the Sun and stars. Following de Groot's retirement in 1994, Mark Edward Bailey was appointed Director in 1995.

Current research at Armagh concentrates on stellar astrophysics including star formation and astrophysical jets, solar system studies, extrasolar planetary systems, and solar system–terrestrial relationships. Stellar astrophysics problems being investigated include helium stars and the late stages of stellar evolution, star-spots and stellar activity, and the heating mechanisms of the Sun's outer atmosphere corona. Spacecraft, such as YOHKOH (Japanese for Sunbeam) and the Solar and Heliospheric Observatory (SOHO), are being used in these solar studies, while solar system research includes the study of the formation and dynamics of comets and asteroids. Solar system–terrestrial studies are concentrated on how solar activity and interplanetary constituents affect the Earth's climate.

Armagh Observatory is one of the principal providers of astronomical research in Northern Ireland. In recent years, baseline support for its activities, together with those of the Armagh Planetarium, has come from the Department of Education Northern Ireland (now the Department of Culture, Arts and Leisure), while much of its research is funded through grants from the UK PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL.

University and College Departmental Astronomy

National University of Ireland

University College Cork. The Crawford Observatory of University College Cork was built in the 1870s by Howard Grubb. Its general plan is in the form of a Gothic-style two-storey central section flanked by two single-storey east–west wings. Grubb was awarded a gold medal at the Paris Exhibition of 1878 for the design and construction of the main instrument, an 8 in refractor. The mounting was modified in the 1890s to incorporate a 13 in astrograph as well as the 8 in refractor. The transit circle, probably the best preserved in Ireland today, employed a novel design in that the declination scales were inscribed on glass and read with transmitted light. The Observatory, which is undergoing some renovation, also houses Grubb's unique 4 in siderostatic telescope designed primarily for solar spectroscopic research.

Current astrophysical research includes investigations into cosmic-ray showers, cosmic-ray bursts from supernovae, cataclysmic astrophysical events, and low-mass x-ray binaries. Other fields of study are in gamma-ray and neutrino astrophysics. Infrared, optical and x-ray observations of white dwarfs, neutron stars and black hole candidates are made using ground-based (Keck, Hawaii) and space-based (ROSAT) observatories.

In addition, Hamiltonian quantum and other gravity theories, and mathematical aspects of supergravity, and super- and cosmic-string theory are investigated.

University College Galway. Atmospheric physics. The studies of the Earth's atmosphere include the greenhouse effect, ultraviolet radiation and air pollution. A field study at Mace Head, Co Galway, is part of the global environmental measurement program.

Gamma-ray astronomy. This research group uses a 10 m reflector on Mt Hopkins, Arizona, USA, for collecting faint Cherenkov light flashes produced in the upper atmosphere which have their origin in supernova remnants (SNRs) and AGNs.

Optical astronomy. Research areas include high-speed optical photometry of pulsars and globular clusters and the use of adaptive optics and other image-sharpening techniques in large telescopes including laser guide stars.

National University of Ireland at Maynooth. Stellar and planetary atmospheres. Collaborations with NASA's JET PROPULSION LABORATORY (JPL) on Lyman α emission from atomic hydrogen, excited by electrons, have provided input into stellar and planetary atmospheric models.

Submillimeter astronomy. This includes studies of interstellar clouds in the Galaxy and other, active, galaxies. This group also participates in the Planck Surveyor Cosmic Microwave Background EUROPEAN SPACE AGENCY (ESA) mission, scheduled for launch in 2005.

Gamma-ray astronomy. This team uses the 10 m telescope of the Whipple Observatory in Arizona to detect extremely energetic radiation from galactic and extragalactic sources, mainly AGNs.

Atmosphere. This involves study of the region 80–250 km, especially the mesopause (80–100 km), for nightglow emissions at optical and infrared wavelengths.

Space Technology Ireland Ltd. Among the projects in which this group is at present involved are the design and construction of spacecraft instrumentation for Gravity Probe B (NASA), Phoenix (ESA), Mars Express (ESA) and Rosetta (ESA). Experiments currently returning data to the Space Technology Ireland (STIL) group are Ireland's LION instrument on ESA's SOHO Mission which was built at STIL and the WAVES instrument on NASA's WIND Mission.

Regional technical colleges

Cork Institute of Technology. Current astrophysical research includes investigations into rapid variability in radioloud quasars and BL Lac objects and microvariability in both radioquiet and radio-intermediate quasars. Observations are taken at multifrequencies in collaboration with international partners. Other fields of study include observations of low surface brightness galaxies and blue compact galaxies. Observations for the various programs are taken at La Palma, Calar Alto, SAAO and with the ASCA satellite.

Galway–Mayo Institute of Technology. Astrophysics. This recent research initiative in astrophysics has been closely involved with the Whipple Gamma-ray Collaboration

which operates an atmospheric Cherenkov imaging detector on Mt Hopkins, Arizona. The system comprises a 10 m optical reflector with an imager made of over 300 photomultiplier tubes and is used to detect compact sources of very-high-energy cosmic gamma-rays from pulsars and AGNs.

University College Dublin.
Astronomical research. This includes star formation and the study of blue compact dwarf galaxies and aspects of galaxy formation. Recent work includes investigations of the emission mechanisms for TeV cosmic ray sources and gamma-ray bursters (GRBs) using NASA's COMPTON GAMMA RAY OBSERVATORY, and searching for flaring and quiescent counterparts of these objects using optical and radio telescopes, such as the WESTERBORK SYNTHESIS RADIO TELESCOPE.

Dublin Institute for Advanced Studies (DIAS)
The DIAS was established in 1940 under the Institute for Advanced Studies Act of 1940 with two constituent Schools, Celtic Studies and Theoretical Physics. In 1947 a third School, Cosmic Physics, was established, itself divided into three Sections, Astronomy, Astrophysics (formerly Cosmic Ray) and Geophysics.

The central administration is located at 10 Burlington Road, Dublin 4, the Geophysics and Astrophysics Sections of the School of Cosmic Physics are at 5 Merrion Square, Dublin 2, and the Astronomy Section is located at Dunsink Observatory, Castleknock, Co Dublin. The DIAS is principally supported by an annual grant in aid from the State, and undertakes research and postgraduate student training.

Current research interests in the Astrophysics Section include plasma astrophysics, especially particle acceleration theory, and outflow phenomena associated with star formation. The Astronomy Section concentrates on advanced stages of stellar evolution and extragalactic x-ray astronomy. The School of Cosmic Physics has been involved in a number of space missions and is currently contributing to the optical monitor for INTEGRAL. Through the La Palma agreement it coordinates access to modern observational facilities.

Queen's University Belfast
Astronomical research is carried out at The Queen's University of Belfast in the Astrophysics and Planetary Science (APS) Research Division of the School of Mathematics and Physics. Two experimental programs on the upper atmosphere (led by Sir David Bates) and solar physics (Dan Bradley) combined about 30 yr ago. The APS Division was born out of this merger.

Initial activities of the group included the development of instrumentation for rocket and balloon flights and for ground-based telescopes. The current APS Division carries out observational astrophysics using ground-based optical and radio telescopes. Space observatories, such as SOHO, ISO and the Hubble Space Telescope, are also used extensively. The main thrust of the group is in astronomical spectroscopy and imaging in a number of areas of Galactic astrophysics. These include studies of the Sun and other stars, the interstellar medium and gaseous nebulae. A solar system research group investigates the origin and distribution of comets and asteroids. The APS Division is also involved in vigorous undergraduate and postgraduate teaching programmes, with some students carrying out their research projects at the Armagh Observatory. Queen's University and Armagh Observatory together form the Northern Ireland Node of the STARLINK computer network.

Private observatories and individuals

Birr Castle (Earl of Rosse)
William Parsons, Lord Oxmantown, later THIRD EARL OF ROSSE (1841), was educated at Trinity College and Magdalen College Oxford graduating in mathematics in 1822. He began telescope making in 1827, and completed a 72 in reflector in 1845 with which he discovered that year the spiral nature of the galaxy Messier 51 (M51, later named the Whirlpool galaxy) and similar structure the following year in the galaxy M99. Spectral studies of eleven nebulae were carried out using the giant reflector, known as the 'Leviathan of Parsonstown'. William's son, Laurence, later the FOURTH EARL OF ROSSE (1867), conducted lunar temperature measurements. Laurence's brother, (later Sir) Charles, was the inventor of the steam turbine. Otto Boeddicker produced an elaborate naked-eye map of the Milky Way in 1892. Sir CHARLES PARSONS purchased the equipment of Sir Howard Grubb and established the firm of Grubb-Parsons in Newcastle-upon-Tyne.

Markree Castle (E J Cooper)
This observatory was founded in Sligo in 1831 by Edward Joshua Cooper. Cooper purchased a 13 in Cauchoix objective and mounted it on a wooden stand at Markree. At the time, this was the most powerful refracting achromatic telescope in the world. Other equipment belonging to Cooper was a Troughton transit instrument (1831), a meridian circle with 7 in telescope by Ertel (1839) and a comet seeker by Ertel (1842). In a ROYAL ASTRONOMICAL SOCIETY report dated 1851, Markree Observatory was described as 'the most richly furnished private observatory then known'. Andrew Graham discovered the minor planet, (9) Metis, there in 1848, computing its orbit and analyzing its irregularities. A four-volume ecliptic star catalogue was also produced. The observatory ceased functioning in 1902.

Daramona Observatory (W E Wilson)
Founded in 1871 by William Edward Wilson in Streete, Co Westmeath, this observatory flourished until 1908. It was equipped with a 12 in Grubb reflector (1871) and a 24 in reflector with which the first photoelectric measurements of stars were made in 1895. The transits of stars were recorded by photography. A measurement of the effective temperature of the Sun was published in 1902.

Millbrook Observatory (J Birmingham)
From 1866 until 1884, the observatory of John Birmingham was in operation near Tuam, Co Galway. Equipped with a 4.5 in refractor, Birmingham compiled a catalogue of red stars. He also made observations of variable stars, sunspots and meteor showers.

Sherrington Observatory (W Erck)
The observatory was established in Co Wicklow by Wentworth Erck and operated from 1877 until 1890. Instruments included an Alvan Clark 7.5 in refractor, formerly owned by Dawes, and a 15 in reflector. Studies undertaken comprised solar disk observations and measurements of the motion of Jupiter's Great Red Spot.

J E Gore's Observatory (1879–1910)
John Ellard Gore founded his observatory first at Ballysodare, Co Sligo, then at 3 Northumberland Road, Dublin. His equipment included a 3 in refractor, and he produced a catalogue of variable stars, and a list of binary system orbits.

W S Monck's Observatory (1888–1915)
William Stanley Monck's observatory was situated at Earlsfort Terrace in Dublin. He employed a 7.5 in refractor and made the first photoelectric observations of planets. He came close to discovering the underlying nature of the diagram now named after Hertzsprung and Russell.

Edgeworth K E (1880–1972)
KENNETH ESSEX EDGEWORTH was born at Daramona House, a few years after his uncle W E Wilson had established his observatory there. Edgeworth had a military career, but he contributed to a wide variety of topics including electrical engineering, economics and astronomy. His main astronomical writings concerned the origin, structure and development of the solar system. In 1943, he predicted the existence of a large reservoir of potential comets occupying the region of space beyond the orbit of Neptune. An object, later named 1992 QB_1, was detected in this region in 1992 by David Jewitt and Jane Luu. This trans-Neptunian object was in fact the first of the Edgeworth bodies to be identified. GERARD KUIPER also made a similar postulation concerning the region at the edge of the planetary system in 1951, and this part of the solar system is now referred to as the Kuiper belt or Edgeworth–Kuiper belt.

Astronomical societies and groups

The Irish Astronomical Society (IAS)
The Irish Astronomical Society was founded in Dublin in 1937, in the same year as Dunsink Observatory was closed. On 1 October 1937, Joseph MacDermott published a letter in the *Dublin Evening Mail* suggesting the formation of a popular Dublin Astronomical Society. A group of 12 interested amateur astronomers responded to the letter and held a meeting in the Red Bank Restaurant. At that meeting, they formed the Irish Astronomical Society and appointed Mr MacDermott as Honorary Lecturer. The Society rented premises at 5 South Leinster Street and held its first Annual General Meeting at Jury's Hotel, Dame Street, on 21 March 1938. Later, during the Second World War, the Society met at 3 Burgh Quay with Uinsionn S Deiseach as resident lecturer.

From the 1950s onwards, many professional astronomers gave lectures to the Society, and by public expression in the newspapers moves were started to make the Society more widespread. After consultation with the Society in Dublin, it was agreed that various Centres should be established; the original IAS would now be the Dublin Centre of the IAS. Centres were established in Belfast (18 October 1946), Armagh (3 December 1946), Londonderry (4 November 1948), Clonmel, Cork and Galway. The Constitution and By-laws of the Society were formally adopted at the first council meeting at Armagh Observatory on 14 June 1947. A Council was in overall control of the Centres and comprised nominees from each Centre in addition to the Directors of Armagh and Dunsink Observatories.

Most of these Centres gradually declined and by the early 1970s only Dublin and Belfast remained. A revision of the Constitution was proposed in 1970 and a meeting was called to be held in Dundalk in November 1971 to consider the proposed revision. Because of the civil unrest then prevailing in Northern Ireland, the Belfast Centre felt it was unwise to travel across the border and the meeting never took place. In 1974, the Belfast Centre proposed the setting up of an essentially new Society having its secretariat based at the Armagh Planetarium. At a meeting of delegates in April 1974, the Dublin Centre succeeded in having this proposal rejected, but a short time later the Belfast Centre withdrew its affiliation with the Dublin Centre and created an independent organisation: the Irish Astronomical Association. As a result, the Dublin Centre is now, once again, the Irish Astronomical Society, holding a regular program of meetings and lectures, with a secretariat at PO Box 2547, Dublin 14 (telephone 00-353-1-298-0181). Publication: *Orbit*.

The Irish Astronomical Association (IAA)
The Irish Astronomical Association came into being when the Belfast Centre of the Irish Astronomical Society withdrew its affiliation with the IAS in the season 1973–4 (see previous section). The IAA was initially envisaged as an all-Ireland organization, with headquarters at the Armagh Planetarium and meetings to be held in both Belfast and Armagh. Nowadays, the Association is primarily active only in and around Belfast, although attracting members from the whole of Ireland, and it focuses its activities on a regular program of meetings and lectures. The IAA can be contacted c/o Mr R McLoughlin, 31 Manse Road, Ballygowan, Co Down, BT23 6HE. Publication: *Stardust*.

Astronomy Ireland
The most recent major amateur astronomical society to emerge in Ireland has been Astronomy Ireland, created

in July 1990. The organization concentrates on astronomy and space science. Two lectures are held in Dublin each month from September to April, given by professional and amateur astronomers. The headquarters of the organization is at PO Box 2888, Dublin 1. Publication: *Astronomy & Space*.

Other societies

Cork Astronomy Club, c/o Mr Charles Coughlan, 12 Forest Ridge Crescent, Wilton, Cork (telephone 00-353-21-543669). East Antrim Astronomical Society, c/o Mr John McConnell, 56 The Meadows, Glen Road, Maghaberry, Moira (telephone 028-9261-9936). Shannonside Astronomy Club, c/o Mr Mike Murphy, Newmarket-on-Fergus, Co Clare (telephone 00-353-61-368025). Tullamore Astronomical Society, c/o Mr Sean McKenna, 145 Ardan Vale, Tullamore, Co Offaly (telephone 00-353-506-41983).

The Astronomical Science Group of Ireland (ASGI)

The Astronomical Science Group of Ireland was formed in 1974 as a collaborative forum for professional astronomers, physicists and technicians in both Northern Ireland and the Republic. The ASGI is currently an umbrella organization including members from all the observatories and university departments in which astronomical research is carried out, and also many of the smaller groups and societies. Meetings are held biannually in spring and autumn at each of the principal affiliated research institutions, in rotation. Financial support for the Group comes from an annual subscription from each of the affiliated groups or institutions, while the Group's affairs are managed by a small executive, comprising a Chairperson and a Secretary. Some of the papers presented at the ASGI have been published in *The Irish Astronomical Journal*.

Iron Meteorite

A meteorite composed mainly of nickel–iron, with traces of other metals; also referred to simply as an *iron*, and formerly known as a *siderite*. Irons account for over 6% of all known meteorite specimens. They are the easiest type to identify, being heavy, magnetic and rust-colored; their metallic sheen tarnishes quickly on the Earth's surface, but otherwise irons show better resistance to weathering than do other meteorites. Iron meteorites are believed to have originated from the cores of asteroidal parent bodies which differentiated before being shattered by impact. They are divided into three main classes according to the crystal structure and nickel content of the nickel–iron: *hexahedrites* (4–6% nickel), *octahedrites* (6–12%) and *ataxites* (over 12%). When sectioned, etched and polished, hexahedrites reveal a fine rectangular grid of so-called *Neumann lines*; octahedrites display a hexagonal hatching known as the *Widmanstätten pattern*; while ataxites show no obvious characteristic. The largest known meteorites are irons. The two most massive are the Hoba (Namibia, ataxite, 60 tonnes) and Cape York (Greenland, octahedrite, 58 tonnes total) meteorites.

Irregular Galaxy

A galaxy with an irregular appearance and no well-defined shape or structure. Irregular galaxies can be divided into two broad classes, designated Irr I and Irr II. Irr I galaxies contain many OB associations (clumps of hot, young, highly luminous stars) and HII regions (luminous clouds of ionized hydrogen that surround hot young stars) and significant quantities of gas (typically about 20% of the total mass is in the form of gas). Some of them contain hints of incipient spiral structure. Their masses range from about a hundred million (10^8) solar masses to several billion ($\sim 3 \times 10^9$) solar masses and their diameters from about 3000 to about 30 000 light-years. Irr II galaxies are amorphous in general appearance and often contain substantial amounts of gas and dust. Some have distorted shapes that appear to have been caused by collisions, or close encounters, with other galaxies or by violent internal activity.

Isaac Newton Group of Telescopes

The largest optical telescope for astronomy in Western Europe stands on the rim of an extinct volcano at an altitude of approximately 2350 m on the island of La Palma, part of the Canary Islands archipelago. The 4.2 m William Herschel Telescope, together with the 2.5 m Isaac Newton Telescope and the 1.0 m Jacobus Kapteyn Telescope, form the Isaac Newton Group of Telescopes (ING). First scheduled use by astronomers started in May 1984, and since then thousands of research projects have been carried out. Many ground-breaking discoveries have been made using these telescopes, such as the first detection of the optical afterglow of gamma-ray bursts, the discovery of black holes in binary star systems, and the study of supernova explosions in distant galaxies.

The Isaac Newton Group of Telescopes aims to deliver an effective telescope operation and a coherent instrument development program to facilitate the execution of world-class astronomical research. The construction, operation, and development of the ING telescopes is the result of a collaboration between the United Kingdom, the Netherlands and Eire. The telescopes are operated on behalf of the UK Particle Physics and Astronomy Research Council and the Nederlands Organization for Scientific Research. The observatory site 'Roque de los Muchachos' is provided by Spain. The ING comprises approximately 65 staff.

For further information see http://www.ing.iac.es/.

Ishtar Terra

One of the three large upland regions of Venus (the other two being Aphrodite Terra and Lada Terra), situated in the planet's northern hemisphere and centered at 70.4 °N, 27.5 °E. In its greatest dimension it measures 5609 km. It takes its name from a Babylonian goddess of love. The western end of Ishtar Terra is dominated by the pear-shaped volcanic plateau Lakshmi Planum, 2343 km across. The plateau contains two large calderas, Colette Patera and Sacajawea Patera, and is bounded to the northwest and southwest by mountain ranges, named Akna Montes and Danu Montes respectively, and to the north and northeast by Frejya Montes. To the east of Lakshmi lies Maxwell Montes, the highest mountain range on the planet. The eastern end of Ishtar consists of Fortuna Tessera, a less elevated area covered with a complex of intersecting troughs and ridges. Fortuna, and the other tesserae to the north and west of Lakshmi, result from lateral compression, part of the complex deformations that occurred on Venus before the lava eruptions in surrounding lowland regions.

Islamic Astronomy

With the advent of Islam in the seventh century, and the swift creation of the largest empire known to medieval man, the civilization that it produced was the expression of the intellectual potential of that sprawling empire which stretched from the Pyrenees in the west to the Central Asian steppes in the east and the Indian subcontinent in the southeast. The very vastness of this empire required for its administration new scientific and technological resources. Some of those resources were already available from more ancient civilizations, others had to be created afresh.

The legacy from the past

The more ancient sciences that the Islamic civilization could draw upon were the Greek, the Persian, the Indian and indirectly the more ancient Babylonian ones. But the Greek legacy was by far the most important, perhaps because of its coherence as it was articulated within the Aristotelian cosmological framework. It is not surprising, therefore, to find the Greek astronomical tradition exacting the lion's share of the concerns of the Muslim scientists who began to forge their own tradition from the very dawn of their own civilization. The major astronomical texts that were resuscitated from the Greek tradition and were translated very early into Arabic—the lingua franca of the Islamic civilization—were essentially the three most important works of PTOLEMY (*fl.* AD 150): the *Almagest*, the *Planetary Hypotheses*, and the *Handy Tables*, the last being quickly superseded by the more up-to-date Islamic astronomical handbooks that pushed it out of circulation.

The other two texts of Ptolemy received the full attention that they deserved at the hands of the Muslim astronomers. But even as they were being translated they were also critically assessed. In the earliest surviving translation of the *Almagest*, that which was completed in the year AD 829, we find attempts to correct the perceived mistakes of the Greek original, as in the case of the value of the synodic lunar month.

But the *Almagest* contained other real mistakes, as we shall see. In it Ptolemy lays down the foundation of Greek astronomy starting with the basic cosmological and mathematical underpinnings of that astronomy, and proceeding to the observations of the phenomena themselves—always giving the mathematical models with which such phenomena could be saved, and the positions of the naked-eye planets that could be predicted. The most basic astronomical parameters of Greek astronomy are determined in this work.

In the *Planetary Hypotheses*, Ptolemy went a step further, by modifying some of the parameters he had determined in the *Almagest*, but most importantly by explicitly re-formulating the same Aristotelian cosmological principles of Greek astronomy, which were only assumed in the *Almagest*. The motion of the same planets could now be materially accounted for by the motion of the real spherical bodies that were supposed to carry them. Furthermore, Ptolemy even hoped to exhibit these motions with planetaria-like constructions.

The reform of astronomy

The sheer time that separated the translators of the *Almagest* from Ptolemy himself was sufficient to show some discrepancies between the original text and the observations the Muslim astronomers were conducting as they were translating. Parameters such as the rate of precession, the inclination of the ecliptic, the eccentricity of the solar orbit—and the resulting maximum solar equation, as well as the motion of the solar apogee (assumed fixed by Ptolemy)—were all found to be erroneous. To rectify the situation Muslim astronomers undertook new observation programs, built larger and more accurate instruments, and most importantly began to question the observational methods of Ptolemy that led to the errors in the first place. To give only one example, it was quickly realized, sometime during the early part of the ninth century, that Ptolemy's method for determining the solar eccentricity which depended on the observation of the Sun at the solstices was in itself flawed, because the variation of the solar declination at those points was indeed very hard to observe with the instruments of late antiquity and medieval times. Hence a new observational method was devised in which the critical observations were conducted in the middle of the seasons where the same variation is much easier to detect. The new method immediately yielded the desired fruits, and from the ninth century onward one would rarely find an Arabic astronomical source that would quote the Ptolemaic parameters. Instead one finds the improved ones that were determined during Islamic times.

On the level of instruments, in addition to building larger instruments, there were also developed new methods for perfecting older ones and for surpassing them in conception. Although the ASTROLABE was known from Greek times, new methods of projection were devised for the instrument as early as the ninth century which deployed new trigonometric techniques that were unknown from the Greek sources and are still essentially the same now. During the same period other mathematical fields such as algebra were also being re-formulated along lines that were not known from Greek times. The religious requirements that may have contributed to the re-formulation of such fields may have also given rise later on to new fields such as *mīqāt* (timekeeping) in which both spherical trigonometry and applied astronomy were brought to full maturity. The projection of astrolabes itself continued to be developed throughout Islamic times, and reached such heights that universal plates were later on devised that could be used anywhere on the globe.

The determination of basic parameters that made the Ptolemaic *Handy Tables* quickly obsolete also gave rise to the construction of new astronomical handbooks which included mainly mean motion and equation tables. They continued to develop and to evolve into more useful and 'user-friendly' tables throughout the Islamic period as well.

Faced with a Greek astronomical legacy whose observable errors became widely known from the earliest

Islamic times, the level of criticism directed at that legacy was also developed at the same pace. The same cosmological principles that were assumed in the *Almagest*, and enunciated more explicitly in the *Planetary Hypotheses*, when examined with a critical eye were also found to produce other theoretical problems of their own that were not considered in the Greek corpus. In essence those problems touched upon the very foundation of Greek astronomy, namely the principle of consistency between the accepted principles and the results derived therefrom. For example, it was quickly realized that although Ptolemy had stipulated in both the *Almagest* and the *Planetary Hypotheses* that he would follow the Aristotelian cosmology he then went on to violate it at almost every turn in those two books. These violations were noted very early on, and the first treatise that has survived in which such cosmological issues were discussed comes from the same first half of the ninth century. Other works were also motivated by the same concern. Collectively such works formed yet another new field that was not known in Greek, namely the field of *'ilm al-hay'a*, which focused mainly on the issue of consistency between the cosmological principles and the mathematical representations of those principles. For reasons that have to do with the general intellectual and religious environment of the time, the new discipline, *'ilm al-hay'a*, also distinguished itself by steering away from the religiously condemned discipline of astrology, in which Greek astronomy was heavily mired, and at the same time devoted itself only to planetary theories without much emphasis on practical astronomy. From the very beginning, therefore, we note the emergence of an Islamic astronomy which was new in its conception, scope and philosophical foundation.

Planetary theory in Islamic astronomy

Nowhere were the inadequacies of Greek astronomy more pronounced than in the planetary theories that included them (see PLANETARY THEORY FROM EUDOXUS TO COPERNICUS). To take only one example of the gross violation of the principle of consistency, Ptolemy had accepted the Aristotelian cosmological principle of uniform circular motion for the celestial spheres, but then when he came to describe the motions of the particular planets, and the spheres that carried them while they moved so that they would not create void, he resorted to mathematical models which required for all the planets, with the exception of the Sun, the uniform motions of those physical spheres around axes that did not pass through their centers. That in itself is impossible, and thus all the results derived from such models, although mathematically feasible and able to produce rather reliable predictions for the positions of planets, were nevertheless cosmologically absurd.

Beginning with the eleventh century, the criticism of these features of the Greek astronomical tradition became more focused and much more elaborate than before, thus producing books with such titles as *Doubts Regarding Ptolemy*, or *Recapitulation in Regard to Ptolemy*. In later centuries, the same violations committed by Ptolemy began to be codified in separate books called *Ishkālāt* (Problems, or Doubts). The natural result engendered by such systematic criticism was the production of alternative mathematical models that could at once be cosmologically feasible, account for the observations, i.e. save the phenomena, and still predict the positions of the planets with an accuracy as good as that predicted by Ptolemy if not better.

In the same eleventh century new attempts at constructing new models that would meet those strict requirements were first conceived but without meeting with much success. However, in the centuries that followed this activity became the most prevalent activity, and one astronomer after another would expend great efforts to produce such new mathematical models. The new discipline dealing with these planetary theories, the *'ilm al-hay'a*, was the natural home for such discussions.

Thirteenth-century development

The thirteenth century saw the establishment of one of the most elaborate astronomical institutions of medieval Islam, the Marāgha Observatory, which was founded by the astronomer and first director Naṣīr al-Dīn al-Ṭūsī (died 1274) in 1259, and his colleague who built the instruments for that observatory, Mu'ayyad al-Dīn al-'Urḍī (1266), where they were both joined later by Ṭūsī's student Quṭb al-Dīn al-Shīrāzī (1311) and collaborator Yaḥyā b. Abī al-Shukr al-Maghribī (1286) and others. As a result, the activity of rebuilding planetary theories with new mathematical models that were not plagued by the inadequacies of the Greek models began to move to more sophisticated grounds.

In their pursuit of such models, both Ṭūsī and 'Urḍī had to devise new mathematical theorems and to reconfigure their own mathematical models in order to accomplish the required motions of the celestial spheres, always working with the same Ptolemaic assumption that those spheres had the same properties stipulated by Aristotelian cosmology. In figure 1, 'Urḍī's lemma simply stipulated that if two lines, AG, DZ always formed equal angles with line AZ, either internally or externally, then the line GD joining their extremities would always be parallel to line AZ. When applied to the model of the upper planets as in figure 2, now marked by the line connections designated as 'Urḍī (Shīrāzī), that theorem will demonstrate that lines ZD and KL will always be parallel. This arrangement will then allow the epicyclic center of the planet Z to move uniformly around the center of its own sphere L, which in turn moves uniformly around the center of its own carrier K, which is placed from the observer at point Q at a distance equal to one and a half times the Ptolemaic eccentricity e. Note that in this arrangement, as required by the Aristotelian cosmology, all the spheres move in place around an axis that passes through their centers, unlike the Ptolemaic configuration, also illustrated in figure 2, where the sphere with center T moves uniformly around the equant D. The

Dirac House, Temple Back, Bristol, BS1 6BE, UK

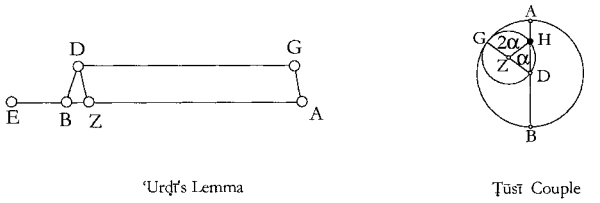

Figure 1. Mathematical theorems for the motions of the celestial spheres: (*a*) 'Urḍī's lemma; (b) Ṭūsī couple.

only violation of Aristotelian cosmology left is that the spheres proposed first by 'Urḍī, who was then followed by Shīrāzī, are still eccentric just as in the Ptolemaic model. But that is an easy hurdle to overcome for it can be assumed that the said eccentricity QK, if need be, could be substituted for by an epicycle and a concentric as was done by APOLLONIUS and Ptolemy after him when they demonstrated mathematically the equivalence between eccentric and epicyclic models. In fact, the connection designated in the same figure 2 with the name of the fourteenth century Damscene astronomer Ibn al-Shāṭir (1375) achieved just that. For, as it can be easily seen, all the connections proposed by this astronomer are strictly geocentric, as required by Aristotelian cosmology. His response to the deployment of epicycles, which could still be conceived as violating that cosmology, is that the epicycles of the largest planets are much smaller than some of the fixed stars and if Aristotle accepts that such fixed stars are made of the same element as the surrounding sphere that carries them then he would have to accept the same kind of composition in the heaven produced by the presence of such small epicycles.

Finally, when the Sun is held fixed, and the Earth is allowed to move around it, as stipulated by Copernican astronomy, we note in figure 3 that the same theorem first proposed by 'Urḍī is still deployed to assure the parallelism of lines OD, NK and their equivalents in the Copernican model. The theorem employed by NICOLAUS COPERNICUS was not enunciated as a new theorem as was done by 'Urḍī, nor was it proven by Copernicus as was done by 'Urḍī, and had to wait until KEPLER wrote to Maestlin asking him about it where he received the proof with the response.

Similarly, the theorem now called the Ṭūsī Couple (figure 1), which was first proposed in 1247 by Ṭūsī, was also used by both Ibn al-Shāṭir and Copernicus in their account for the motions of the planet Mercury. The theorem itself stipulates that if two spheres AGB, and GHD, where the diameter AD is twice the length of GD, are made to move in such a way as the bigger sphere moves in place at uniform speed and the smaller sphere moves in the opposite direction at twice that speed, then the original point of tangency H will oscillate back and forth along the diameter of the larger sphere, thereby creating linear motion out of uniform circular motion. Ṭūsī used that theorem to account for the motions of the Moon (not illustrated) and the upper planets as seen in figure 2.

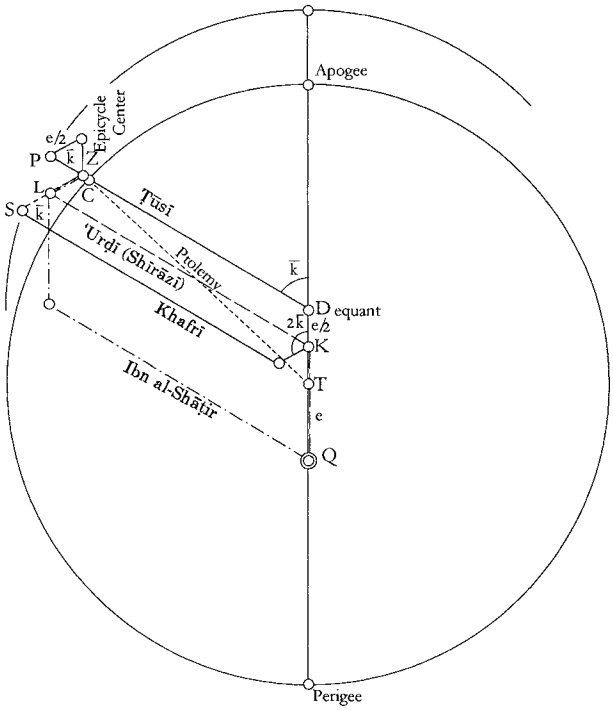

Figure 2. Mathematical models applied to the motions of the upper planets.

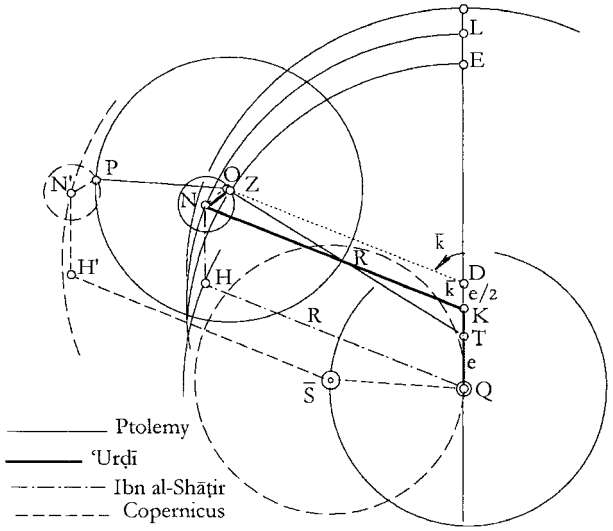

Figure 3. Comparison of the models of Ptolemy, 'Urḍī, and Ibn al-Shāṭṭir with the Copernican model.

With those two theorems being the only additions made by Copernicus to the Ptolemaic models (heliocentricity excepted) it becomes very clear that the mathematical developments that were devised in the Islamic world were themselves the same ones deployed by Copernicus.

Islamic astronomy in the sixteenth century

But by the sixteenth century, Muslim astronomers had finally come to realize that all those problems, when stated in the Ptolemaic–Aristotelian fashion, do not in fact have a unique mathematical solution. Figure 2 illustrates the mathematical equivalence of all the solutions proposed, and the person who apparently came to that realization was the same Khafrī (1550) whose configuration for the upper planets is also illustrated in the same figure.

This line of research which was pursued by Muslim astronomers in order to resolve the problems posed by the Greek astronomical tradition seems to have been the same line that was followed by Copernicus in the introduction to his *Commentariolus* (again heliocentricity excepted). From that perspective, it becomes very clear that the Islamic astronomical tradition, which seems to have been passed on to Europe during the Renaissance, was itself embedded in the much larger context of rejecting the Greek astronomical tradition, rather than preserving it as is often asserted.

Isotope

Any of two or more forms of the same chemical element, the atomic nuclei of which contain the same number of protons (and therefore have the same atomic number) but different numbers of neutrons (and therefore have different mass numbers). For example, oxygen has three stable isotopes, oxygen-16, oxygen-17 and oxygen-18, denoted symbolically by ${}^{16}_{8}\mathrm{O}$, ${}^{17}_{8}\mathrm{O}$, and ${}^{18}_{8}\mathrm{O}$, respectively (the subscript denotes atomic number and the superscript, mass number). Each nucleus contains 8 protons, together with 8, 9, or 10 neutrons, in the cases of oxygen-16, oxygen-17, and oxygen-18. Oxygen 16 comprises about 99.76% of naturally occurring oxygen.

See also: atom, neutron, proton.

Isotopes in the Interstellar Medium

ISOTOPES (or isotopomers) of the same chemical element have different atomic weights. The nuclei have different numbers of neutrons, but the same number of protons. For deuterium, ^{2}H or D, the nucleus consists of a proton and neutron; for helium the two stable isotopes are ^{3}He and the much more abundant ^{4}He. NUCLEOSYNTHESIS has changed isotopic and element abundances in the big bang. Subsequently, there were further changes in STELLAR INTERIORS, NOVAE, SUPERNOVAE and COSMIC RAY interactions with interstellar (IS) material. This processing changes the abundance of light elements and isotopes; all elements heavier than lithium must have been produced in stars.

It is generally accepted that the universe began with an explosive event, the *big bang*. About 100 s after the big bang, neutrons and protons produced *primordial* D, ^{3}He, ^{4}He and ^{7}Li. In the standard big bang nucleosynthesis (SBBN) of the *light elements*, the most important parameter is the baryonic density, usually expressed as the baryon-to-photon ratio, η. After expanding and cooling, the ionized material recombined and then formed stars and galaxies. For stars of mass $M \geq 0.08 M_\odot$, nucleosynthesis products are expelled into the interstellar medium (ISM). In the solar system and perhaps in the local interstellar medium (LISM), we can measure samples directly. Accurate IS abundances cannot be deduced from cosmic ray data since the sources and interaction histories are not known in sufficient detail. For regions far from the Sun, we can measure gas phase abundances using spectroscopy, but we cannot determine the constitution of dust grains. Abundance ratios of elements in the gas phase may be affected by differing amounts of condensation onto dust grains; however, such processes will not affect the ratios of isotopes.

Measurements of ISM abundances allow us to constrain the global effect of nucleosynthesis by ensembles of stars, while abundance determinations for the circumstellar regions around individual stars allow us to investigate yields for a given object. In all stellar nucleosynthesis schemes, one must differentiate between *primary* and *secondary* products. Primary products are those produced from H or He in a short time compared with the age of the galaxy, $\sim 10^{10}$ yr. Secondaries are produced from primaries. Thus ^{12}C is a primary, while ^{13}C is a secondary. The abundance of secondaries grows with time relative to the abundance of primaries. The study of *chemical evolution* of galaxies allows us to trace the history of nucleosynthesis; models are constructed to account for the combined effects of nucleosynthesis in individual stars and the ejection of such material into the ISM as well as the conversion of ISM material into stars in the STAR FORMATION process.

In this review, we will emphasize data for selected species and sketch the measurement processes and interpretations needed to obtain abundances. The light elements deserve special treatment because of their relation to the big bang.

Results for D, He and Li

The light element abundances are especially interesting since these provide tests of big bang models and constrain baryon densities in the SBBN (figure 1). The SBBN products will be altered by stellar processing. Separating the effects of SBBN from stellar processing to determine the primordial abundances is a great challenge. We believe that stars *always* net destroy deuterium; ^{3}He and ^{7}Li may be net produced, while ^{4}He is *certainly* net produced. Measurements show that ^{4}He makes up $\geq$20% of the mass of the universe; the other big bang products constitute a mass fraction of $\leq 10^{-4}$. Our Sun has a mass fraction of $\sim$27% helium and 2% metals. Metals, designated as Z, are all elements heavier than helium. Most of the helium was produced in the big bang; when helium is produced in stars, metals are also produced (see CHEMICAL COMPOSITION OF STARS). Solar system metals were produced in earlier generations of stars, expelled into the ISM and incorporated in the protosolar nebula (see SOLAR SYSTEM: FORMATION). The solar system represents material not processed in the last 4.5×10^9 yr, while the ISM is more processed. Compared with both, high-redshift extragalactic material was not very processed since the big bang.

Deuterium

Measurements of Lyman series ultraviolet IS absorption lines in diffuse clouds toward intense background sources provide the most reliable D/H ratios. Most of the D and H in these clouds is atomic, that is D I and H I. Measurements of local gas have been obtained with the International Ultraviolet Observatory (IUE), Copernicus and Hubble Space Telescope (HST). Determinations of D/H ratios are limited by the small abundance of D relative to H and the small velocity shift caused by the different nuclear masses. The radial velocity of a D I feature must be separated from the corresponding H I feature by -82 km s^{-1} and the line widths of H and D must be related. If thermally broadened, the D I linewidth must be equal to 0.7 times that of the corresponding H I feature which is corrected for saturation; if turbulence broadened the widths must be equal. The complexities of INTERSTELLAR CHEMISTRY preclude determinations of D/H ratios from measurements of deuterated molecules such as DCO^+ or DCN. Similarly, a detection of the $\lambda = 92$ cm D I hyperfine transition in a molecular cloud will not bring information about the D/H ratio. More useful for D/H ratios might be measurements of rotational lines of the most abundant deuterated species, HD. However, one needs column densities of H_2, which can be uncertain by factors of 2 or more.

There are two interpretations of measured D/H ratios. In the first, there are significant deviations from the mean value. This interpretation is based on comparisons of H I and D I column densities for clouds along the same line of sight. In the second interpretation, there is a *single* D/H ratio. For the LISM, this is $(1.50 \pm 0.10) \times 10^{-5}$, with a 1σ error. This value and solar system ratios give lower

limits to the primordial D/H ratio. The optical depths of H I may be *the* limit to determinations of galactic D/H ratios. Further progress will come with the FUSE satellite, which will allow measurements of higher transitions to improve estimates of the optical depths of H I. FUSE will also extend measurements of the D/H ratios to regions of different stellar processing in the disk and halo of our galaxy and other nearby galaxies.

For clouds with REDSHIFTS of ∼2.5 or more, one can use Earth-bound optical telescopes to measure D I in the absorption line spectra of quasistellar objects. Accurate D/H ratios also require accurate H I column densities. These require accurate estimates of the optical depths of the H I lines. Large numbers of sources are needed to find unblended D I absorption, since sources with such 'clean' spectra constitute ≤2% of the total. Some observers found a ratio of $\approx 2 \times 10^{-4}$; this may be caused by blending of D I with blueshifted H I. The currently favored high-redshift ('high Z' in figure 1(*b*) and 'early universe' in table 1) ratio is $\mathrm{D/H} = (3.4 \pm 0.25) \times 10^{-5}$. This ratio is consistent with current chemical evolution models, using accepted parameters. From the SBBN relation (figure 1), this ratio allows us to estimate an upper limit to the baryon density.

Helium isotopes

The spectroscopic abundance of neutral helium is difficult to measure. The most reliable ratios are based on lines emitted from regions ionized by high-mass stars, that is regions, or gas, ionized by the extremely hot remnants of evolved stars, PLANETARY NEBULAE (PNe).

^{3}He. Outside the solar system there are two sources of data for ^{3}He/H ratios. The Solar Wind Ion Composition Spectrometer on the Ulysses spacecraft measures the abundance of ^{3}He and ^{4}He atoms. The velocities allow us to separate solar system from LISM abundances. The ratio is $^3\mathrm{He}/^4\mathrm{He} = (2.5^{+0.7}_{-0.6}) \times 10^{-4}$. The quoted statistical error is 3 times the systemic error.

The second ratio is based on radio measurements of the hyperfine transition from ^{3}He$^+$ at 3.46 cm in regions and PNe. The hyperfine line is thermalized and optically thin. There is no ^{4}He$^+$ line, since the ^{4}He$^+$ nucleus has no spin. Models which account for density structure in the ionized gas will raise the ^{3}He$^+$/H ratio; elaborate models give ratios up to a factor of 2 larger than homogeneous models.

Standard stellar models predict that $1M_\odot$ stars which are now PNe should be expelling large amounts of ^{3}He. Observations show that NGC 3242, a PNe with a $1M_\odot$ progenitor, has 100 times the ^{3}He found in the ISM. If ^{3}He were produced in *every* $1M_\odot$ star passing through the RED GIANT phase just now, the ISM should show a ratio similar to NGC 3242. The most likely process destroying ^{3}He in solar-mass stars is extra mixing in the stellar interiors during the red giant phase. This brings ^{3}He into deeper layers where temperatures are higher, enhancing destruction. To be consistent with ISM ratios, at least 70% of the ^{3}He must be destroyed before the PN stage.

In figure 2 there is a gradient in the ^{12}C/^{13}C ratio with distance from the Galactic center. If much ^{3}He were produced in stars, STELLAR EVOLUTION models predict a ^{3}He/H gradient *opposite* to the ^{12}C/^{13}C gradient. The lack of a ^{3}He/H gradient supports the contention that *not* much ^{3}He is produced in stars, so that stellar processing has little effect on the ^{3}He abundance. The average of the ISM data and Ulysses result is $^3\mathrm{He/H} = (2.0 \pm 0.7) \times 10^{-5}$. This should be primordial.

^{4}He. The present measured abundance of helium is an *upper* limit to the primordial mass ratio, y_p. Since the baryon-to-photon ratio, η, is only a weak function of the relative abundance of ^{4}He (see figure 1), even small uncertainties in y_p have *large* effects on estimates of the baryon density (figure 1). Extragalactic optical observations are best for these determinations.

Corrections of measurements to obtain primordial abundances must be empirical, since ^{4}He is produced in an ensemble of stars determined by an initial mass function, which may change with time and location. Also the star formation rate was certainly different in the past. One obtains an estimate of y_p by assuming a linear relation between helium abundance and metallicity, Z (usually the O/H abundance ratio); the traditional value of this relation is $\Delta y/\Delta Z \sim 3$. Extrapolating this relation of to zero metallicity, we can estimate y_p. Measurements have been extended to a larger group of low metallicity, blue compact galaxies (BCGs). Previous data taken have been revised because some He$^+$ spectra were affected by unsuspected line absorption and because of biases in previous fits of Y versus metallicity.

The best estimate of the primordial helium mass fraction, obtained for BCGs, is 0.242. An extrapolation to O/H = 0 gives $y_\mathrm{p} = 0.244 \pm 0.002$ while, for N/H = 0, $y_\mathrm{p} = 0.245 \pm 0.001$. From the BCG data, we adopt a value $y_\mathrm{p} = 0.244 \pm 0.002$.

Lithium

Li is very fragile, easily destroyed in deeper layers of even low-mass stars. Compared with ^{7}Li, the ^{6}Li nucleus is more loosely bound, so is more easily destroyed by nuclear burning. The accepted conclusion is that ^{6}Li is produced by collisions of cosmic rays with atoms; ^{7}Li is produced in SBBN, in spallation and in stellar nucleosynthesis.

In the ISM, the ratio of ^{7}Li/^{6}Li is free from systematic effects. Toward ζ Oph there are two velocity components in absorption with ratios of 8.6 ± 0.8 and $1.4^{+1.2}_{-0.5}$. Toward ρ Oph, the ratio is 11.1 ± 2; toward ζ Per, $5.5^{+1.3}_{-1.1}$. These ratios indicate that there are actual differences. In addition, the solar system ratio, 12.3, is significantly different from those of ζ Oph and ζ Per. This indicates that the ISM is very inhomogeneous and the solar system formed from the ISM like that toward ρ Oph.

For young low-mass stars, that is POPULATION I STARS, observations show a wide range of Li/H ratios. There is no general theory of Li processing in low-mass stars; one must use correlations based on observations. The best estimates

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of primordial Li abundances are based on observations of the older population of stars, that is POPULATION II STARS. For these stars, Li abundances are rather constant for a wide range of $T_{\rm eff}$ and are largely independent of metallicity (estimated from the abundance of iron); this has been referred to as the *Spite plateau*. The simplest explanation is that the mechanisms which destroy lithium in population I stars are absent in population II objects and that the Li in extreme population II stars is primordial. Newer results show that there is at least some Li destruction. There is also a slight increase of Li abundance with metallicity; this is the first direct evidence for stellar Li production. The average observed Li/H value, for upper and lower envelopes, is $(1.16^{+0.6}_{-0.3}) \times 10^{-10}$. If there are unsuspected sources of destruction of Li, one can fit to the *upper* envelope to obtain the ratio $\mathrm{Li_p/H} = (2.5^{+0.7}_{-0.5}) \times 10^{-10}$ (see figure 1(*b*)).

Summary and interpretation of light element abundances

We plot the best estimates of primordial abundances versus the baryon-to-photon ratio η_{10} in figure 1(*b*). For consistency, all the primordial abundances must give a single value of η_{10}. From the data, there is a consistent model for $\eta_{10} = 4.7$. One must use the ^{7}Li/H ratio determined under the assumption that the upper envelope of the measurements is the best choice. The D/H value measured for high-redshift objects must be 3.4×10^{-5}, and the ^{3}He/H ratio must be nearly at the lower limit. The most critical test of SBBN rests with the ^{4}He/H ratio; if the BCG ratios were lowered by 10%, there would be an inconsistency with the D/H ratio.

The best value of η_{10} is 4.7. Because systematic errors dominate, we can only give a range of errors; η_{10} is between 2 and 5. For $\eta_{10} = 4.7$ and a microwave background temperature of 2.73 K, the *baryonic* mass density is 3.2×10^{-31} g cm^{-3}. For a HUBBLE CONSTANT of 65 km s^{-1} Mpc^{-1}, the density needed to halt the expansion of the universe is 25 times larger. Thus, baryons alone cannot halt this expansion.

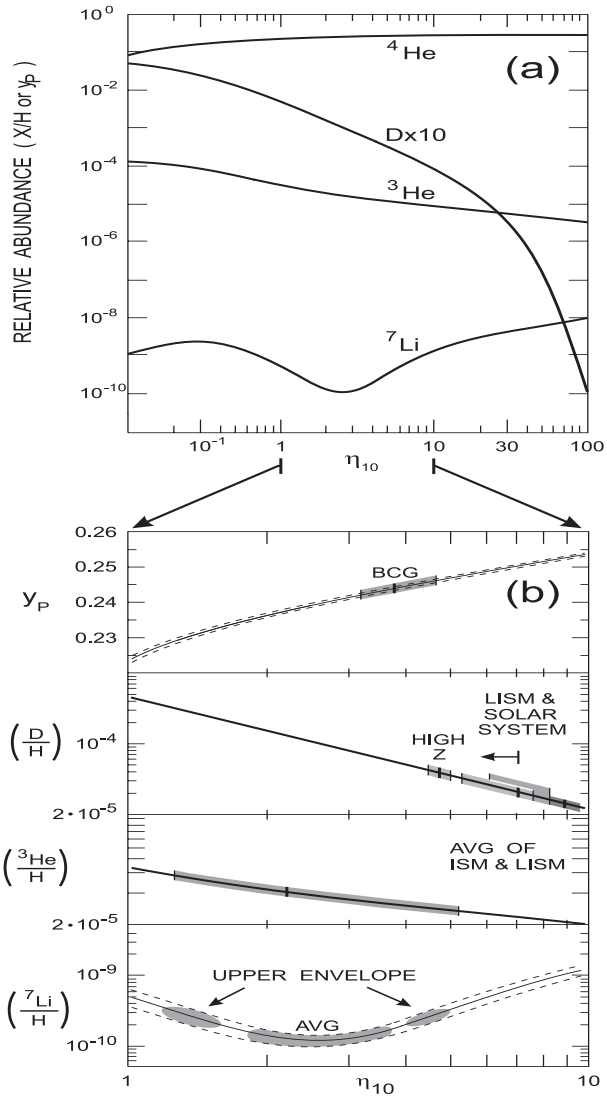

Figure 1. (*a*) The SBBN production scheme as a function of η_{10}, which is 10^{10} times the baryon-to-photon ratio. The number ratios, X, refer to D, ^{3}He and ^{7}Li, the mass fraction, y, refers to ^{4}He. The curve for D is multiplied by 10 for clarity. (*b*) An expanded version of (*a*), showing the region of parameter space where the abundances of the elements are located. The shaded regions show where the data in table 1 are located. In the panel for D/H ratios, the leftward arrow indicates that the solar system and LISM ratios are *lower* limits to the primordial values. For D/H, 'high Z' refers to gas toward high-redshift quasars; the values for lower D/H ratios are from the solar system and LISM. For $y_{\rm p}$, the BCGs are blue compact galaxies. BCGs are essentially very large regions with low metallicity; thus their y values should be close to $y_{\rm p}$. The dashed curves show the uncertainties in the theoretical relations.

Results for CNO isotopes

Isotope shifts of atomic spectra, caused by different nuclear masses, are sufficiently large for light elements, but not for heavier elements. These must be measured by molecular spectroscopy. A comparison of isotopomers might be affected by *selective dissociation* and *chemical fractionation*. Selective dissociation occurs when molecules are destroyed by spectral line radiation; the more abundant species may be self-shielded. Chemical fractionation arises from small differences in the different molecular zero-point vibration energies, related to mass and to the temperature of formation. The result is to enrich the heavier molecular species. If this were a large effect, the measured ^{12}CO/^{13}CO ratio would not represent the ^{12}C/^{13}C ratio. The most reliable carbon isotope ratios are given by CH^+ measurements, because CH^+ is formed only at high temperatures. CH^+ lines are measured in the optical, so these ratios are restricted to the LISM. The best $^{12}CH^+/^{13}CH^+$ ratio is 67 ± 3. From radio astronomy data, the average of 13 sources in the LISM is ^{12}C/^{13}C $= 69 \pm 6$ (table 2). The agreement of the CH^+ isotope ratio with these carbon isotope ratios from RADIO ASTRONOMY indicates that the combined effects of fractionation and selective

Table 1. Selected light element ratios.

Abundance ratio	Protosolar	Nearby ISM	Early universe, BCGs or population II stars
$(D/H) \times 10^5$	2.4 ± 0.5	1.50 ± 0.10	3.4 ± 0.25
$(^3He/^4He) \times 10^4$	1.5 ± 0.3	2.0 ± 0.7	–
Y	0.273–0.277	0.260 ± 0.018	0.244 ± 0.002
$(^7Li/H) \times 10^{10}$	–	–	$1.16^{+0.6}_{-0.3}$ (average of all) $2.5^{+0.6}_{-0.5}$ (upper envelope)
$^7Li/^6Li$	12.3	6.2; 1.4 to 11.1	–

dissociation are small. On this basis, radio observations of CO and H_2CO have been used to determine the $^{12}C/^{13}C$ ratio over the Galaxy.

Nitrogen and oxygen are not affected by chemical fractionation. However, determinations of $^{14}N/^{15}N$ or $^{16}O/^{18}O$ ratios may be influenced, since these ratios are frequently measured as double ratios, $H^{12}C^{15}N$ and $H^{13}C^{14}N$. Then, one uses ratios from CO and H_2CO to obtain the desired results.

Carbon

In figure 2(*a*) we plot the ISM isotope ratio $^{12}C/^{13}C$ determined from H_2CO and CO as a function of D_{GC}. These results show that nearly all the ratios obtained from H_2CO lie above those from CO. This is consistent with interstellar chemistry models. Molecular clouds near the Sun show a higher ratio than clouds in the inner part of the disk of our Galaxy, and the H_2CO ratios have a larger scatter than ratios obtained from CO data. A least-squares unweighted fit to all of the data gives

$$^{12}C/^{13}C = (7.5 \pm 1.9)\, D_{GC} + (7.6 \pm 12.9).$$

The uncertainties are RMS values. There is a large scatter between the data and the fit. Some of this is due to errors, but there is evidence for actual source-to-source differences. If the solar system ratio, 89, represents the LISM 4.5×10^9 yr ago, the ratio has decreased by ∼20%. Taking limits as actual values, optical studies of 191 circumstellar envelopes give an average ratio of 18; radio data (table 2) gives an average of 40. The stellar production of ^{13}C is diluted by a factor of >2 in the LISM.

The $^{12}C/^{13}C$ ratio is a measure of the primary to secondary processing. The ^{12}C is thought to be produced on rapid time scales primarily via He burning in massive stars. The ^{13}C is thought to be produced primarily via CNO processing of ^{12}C seeds from earlier stellar generations. This occurs on a slower time scale primarily during the red giant phase in low- and intermediate-mass stars or novae. The $^{12}C/^{13}C$ ratio for the solar system is 89 (table 2). As a function of time, ^{13}C is expected to increase with respect to ^{12}C, as with all secondary products. Thus, the ISM $^{12}C/^{13}C$ ratio should be lower than the solar system value (table 2); this ratio is only about 20% above the isotope ratio in the LISM. Thus, over the last 4.5×10^9 yr, lower-mass stars have not produced a large amount of ^{13}C in the LISM.

Nitrogen isotopes

To obtain $^{14}N/^{15}N$ ratios from $H^{13}CN$ and $HC^{15}N$ data, $^{12}C/^{13}C$ ratios must be known. We take these from the fit to figure 2(*a*). Applying these results to the HCN data, we obtain the $^{14}N/^{15}N$ ratios plotted in figure 2(*b*):

$$^{14}N/^{15}N = (19.0 \pm 8.5)\, D_{GC} + (288.6 \pm 65.1).$$

The $^{14}N/^{15}N$ ratio in the solar system is 270. Near the Sun, the average is 388 ± 32 (eight sources). From the fit, the value at 8.5 kpc is 450. Both values are consistent with an ∼70% increase in this ratio since the formation of the solar system. The Galactic center region and the CARBON STAR IRC+10216 show high metallicities and $^{14}N/^{15}N$ ratios >500 (table 2). This gives support to the notion that $^{14}N/^{15}N$ ratios are directly correlated with metallicity. If these regions are typical, one expects an increase of $^{14}N/^{15}N$ ratios in the inner Galactic disk. However, the data show a somewhat *lower* value (table 2). Studies of H II REGIONS in the inner part of the Galactic disk have a higher metallicity. Thus, the chemical evolution of ^{14}N and ^{15}N in the inner disk must have been *very* different from that of the Galactic center, the well-known carbon star CW Leo (IRC+10216) or the LISM. These results can be explained if novae are the main contributors to ^{15}N. The $^{14}N/^{15}N$ ratio in the LMC is ∼100. This galaxy is metal poor; this result indicates that the production of ^{15}N is primary and not secondary.

Oxygen

There are three stable oxygen isotopes. Usually, one obtains the $^{16}O/^{18}O$ ratio from a double ratio; for figure 2(*c*), we used $(H_2^{12}C^{18}O)/(H_2^{13}C^{16}O)$. To obtain a ratio involving only oxygen, one must use the carbon isotope ratios (figure 2(*a*)) to separate the contributions of carbon from oxygen. The isotope values are plotted in figure 2(*c*). The fit gives

$$^{16}O/^{18}O = (58.8 \pm 11.8)\, D_{GC} + (37.1 \pm 82.6).$$

The fit is surprisingly good. For five sources in the LISM, the average ratio is 557 ± 30 (table 1). From the fit, the value at 8.5 kpc is 537, with large uncertainties.

Ratios of ^{18}O to ^{17}O show no gradient with D_{GC}. The average value of this ratio is markedly below those

Table 2. Radio data for isotope ratios of heavier elements.

Isotope ratio	Galactic center	Inner Galactic disk	LISM	Solar system	Carbon stars	Nuclei of galaxies
$^{12}C/^{13}C$	∼20	53 ± 4	69 ± 6	89	>30	≥30
$^{14}N/^{15}N$	>600	320 ± 30	388 ± 32	270	>515	–
$^{16}O/^{18}O$	250	327 ± 32	557 ± 30	490	320–1260 >2700	∼200
$^{18}O/^{17}O$	3.5 ± 0.2	3.6 ± 0.2	3.6 ± 0.2	5.5	0.6–0.9 < 1	8
$^{32}S/^{34}S$	∼22	∼22	∼22	22	–	–
$^{29}Si/^{30}Si$	1.5	1.5	1.5	1.5	–	–

of the solar system, but is larger than the carbon star value. The average $^{16}O/^{18}O$ ratio in the ISM near the Sun is comparable with that found in carbon stars, to within the errors. In the inner Galactic disk, the ratio is a factor of 2 lower; the value in the Galactic center is comparable. If the isotopes are formed in stars more massive than $10M_{\odot}$, then ^{16}O is a primary nucleosynthesis product, while ^{17}O is secondary. The major production scheme for ^{18}O is not certain. One expects a radial gradient in a primary/secondary ratio but not in a secondary/secondary ratio. The gradient observed in $^{16}O/^{18}O$ combined with the lack of a gradient in $^{18}O/^{17}O$ indicates that ^{18}O is secondary. However, the observed $^{16}O/^{18}O$ ratio for the LISM, 557 ± 30 (table 2), is larger than the solar system value, 490. This indicates an *increase* with time, whereas primary/secondary ratios should *decrease* with time. Thus, this model cannot reproduce the evolution of either ratio, from comparisons of solar system and LISM ratios. To explain both the temporal and the spatial behavior of $^{16}O/^{18}O$, one must assume that there is an unknown mechanism which has inhibited the ^{18}O production in the last few 10^9 yr. Since the nucleosynthesis of ^{18}O is still not well understood, this is possible. As expected for a purely secondary/secondary ratio, there is no variation of $^{18}O/^{17}O$ with D_{GC}. Observations show a marked decrease in the $^{18}O/^{17}O$ ratio between the formation of the solar system and the present. So far, models have been based on the assumption that only massive stars produce ^{17}O. If ^{17}O is produced in low- and intermediate-mass stars, the $^{18}O/^{17}O$ ratio is a secondary/secondary result, with ^{17}O having a longer production time scale, i.e. more secondary than ^{18}O. Then in the past few 10^9 yr, the abundance of ^{17}O will grow faster than ^{18}O; this explains the decrease of the ratio with time. It is also possible that the solar system is not a representative sample of the ISM 4.5×10^9 yr ago.

Sulfur, silicon, magnesium and aluminum isotopes

For other isotopes, there are fewer data, as compared with CNO results. There is little or no variation in the $^{32}S/^{34}S$ ratio with D_{GC}. The ISM ratio agrees with the solar system value, so there seems to have been no change with time. Additional data show a $^{32}S/^{34}S$ ratio of 24.4 ± 5.0, a $^{34}S/^{33}S$ ratio of 6.27 ± 1.01 and $^{34}S/^{36}S$ of 115 ± 17. The last ratio is lower than the solar system value of 200, so ^{36}S may be a secondary product. This is expected on the basis of chemical evolution models and indicates good agreement. We take this (optimistically) as evidence for the correctness of both.

In the solar system, the $^{28}Si/^{29}Si$ ratio is 19.7. For some sources it is certain that the optical depths of ^{28}SiO lines are moderate, so there can be no direct determination of the $^{28}Si/^{29}Si$ from measurements of the rotational lines of SiO isotopomers. The isotopes ^{29}Si and ^{30}Si have been measured in the Galactic center region. To within the errors, the ratio agrees with that measured for the solar system. Thus, there appears to be no gradient in the $^{29}Si/^{30}Si$ ratio with D_{GC}.

Radioactive nuclei which decay by γ ray emission can be detected with satellites. These data refer to heavier elements ejected into the ISM by larger-mass stars, novae or supernovae. The most well-studied isotope is ^{26}Al; this might be produced during the red giant phase of lower-mass stars.

The presence of ^{26}Al in the ISM is detected by the γ ray emission at 1.806 MeV, from the decay of ^{26}Al to the first excited state of ^{26}Mg. The mean half-life is 1.05×10^6 yr. If supernovae produced *all* of the ^{26}Al, there would be an overproduction of the stable isotope ^{27}Al. It seems likely that ^{26}Al is formed in red giant stars.

An excess of solar system ^{26}Mg in meteoritic samples had been interpreted as evidence that an enrichment of ^{26}Al occurred shortly before the formation of the solar nebula. This may have been a result of triggered formation. A less likely interpretation is that ^{26}Al was produced elsewhere and transported here. The rare stable isotopes of magnesium, ^{25}Mg and ^{26}Mg, have been measured in IRC+10216 using the molecule MgNC. The ratio of ^{24}Mg:^{25}Mg:^{26}Mg was found to be 78:11:11, with a quoted error of ± 1. This result agrees with the terrestrial ratio of 79.0:10.0:11.0.

Summary of isotopomers of heavier elements

There is excellent evidence for a gradient in the $^{12}C/^{13}C$ ratio with distance from the center of the Galaxy, D_{GC}. There is evidence for source-to-source variations; for some ratios, the solar system value does not represent the average of the LISM at the time of formation. There is also

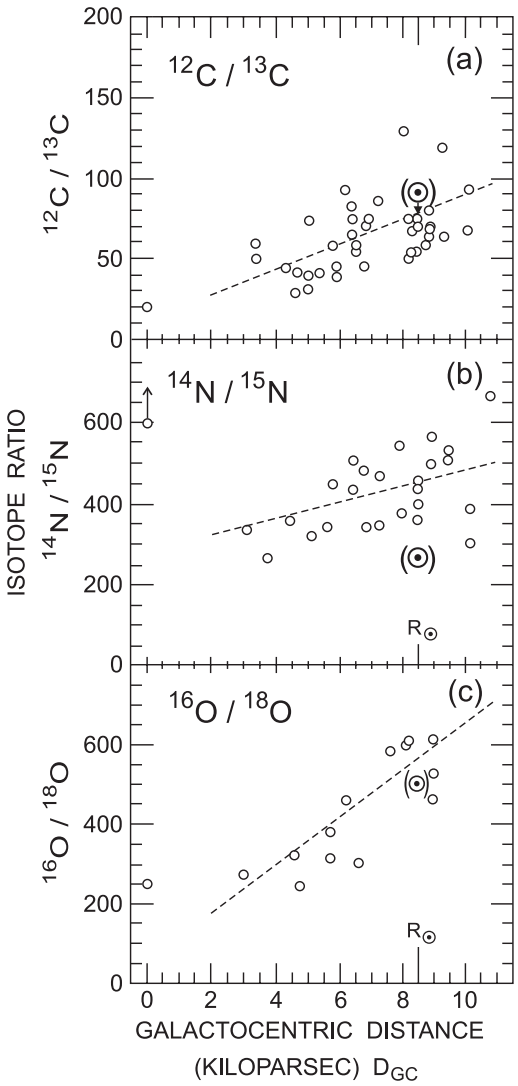

Figure 2. Plots of isotope ratios as a function of distance from the Galactic center, D_{GC}. The distance of the Sun from the center is 8.5 kpc. The lines are unweighted least-squares fits to the data. For carbon and oxygen ratios, the solar system values are shown as (⊙); for nitrogen, the value is the tip of the arrow. (*a*) Data for the $^{12}C/^{13}C$ ratio, from CO and H_2CO. The ratios from CO data lie below those from H_2CO. (*b*) Data for the $^{14}N/^{15}N$ ratio, based mostly on double isotope ratios in the HCN molecule. (*c*) Data for the $^{16}O/^{18}O$ ratio, based on double isotope ratios in the H_2CO molecule. The value at D_{GC} is the average for the galactic center; the $^{14}N/^{15}N$ value is a lower limit.

evidence for a gradient in the $^{16}O/^{18}O$ ratio and reasonable evidence for a $^{14}N/^{15}N$ gradient with D_{GC}. The values of the oxygen ratio near the Sun and the nitrogen ratio in the inner Galaxy cannot be explained on the basis of current theories. Isotopomer studies of the nuclei of external galaxies are just beginning. These results can be important for an understanding of the star formation history in such objects.

Bibliography

The study of isotopomers is driven by data, so the most recent collections are the most useful. The results of a meeting held at the International Space Science Institute, Bern, were used extensively. These proceedings are contained in

Isotopic Anomalies

Until the early 1970s, all models of solar system evolution assumed that the inner nebula underwent a high-temperature stage, destroying all grains and thus erasing the entire presolar record: all solid bodies would have accreted from the cooling of this nebula, constituting a gaseous initial reservoir essentially homogeneous in composition (see SOLAR SYSTEM: FORMATION).

This basic assumption was based on the observation that in all available material, terrestrial or extraterrestrial (lunar samples, meteorites), every element was measured with a fixed isotopic composition. Actually, some tiny differences were observed, but could be explained as resulting from known processes. Let us consider the case of the oxygen isotopes. Oxygen has three stable isotopes, ^{16}O , ^{17}O and ^{18}O , with abundance ratios 99.76%, 0.04% and 0.2% respectively. If for example one compares the O isotopic ratios in water vapor and the liquid water from which it evaporated, one will find a systematic enrichment in light oxygen isotopes (^{16}O), and accordingly a depletion in heavier isotopes (^{17}O and ^{18}O), in the gas phase (the reverse being observed in the liquid). Moreover, this mass-dependent 'fractionation' process is such that, with respect to ^{16}O, the depletion of ^{18}O is 2 times higher than that of ^{17}O. Thus, on a diagram where the $^{17}O/^{16}O$ variation, with respect to a given reference, is plotted against the $^{18}O/^{16}O$ variation, all samples fall on a line ('fractionation line') with slope 1/2, which represents the ratio of mass differences: (17–16)/(18–16) (see figure 1).

In 1969, two major events modified this view. First, the return of lunar samples from the APOLLO missions had forced all experimenters to drastically increase the sensitivity of their analytic tools, to allow measurements to be performed at a microscopic grain scale. Second, a very large 'primitive' meteorite, a carbonaceous CHONDRITE called the ALLENDE METEORITE, fell and was retrieved prior to any contamination. This meteorite contains millimeter-sized white inclusions imbedded in a dark silicate matrix. These inclusions are made of highly refractory minerals, that is very-high-temperature condensates. Although very difficult to measure on such a small scale, their O isotope contents were determined. Very surprisingly, they happened to be quite distinct from any other ever measured, including that of the Allende bulk matrix. Actually, they did not plot on the oxygen fractionation line, but rather on a line with slope 1, the proposed interpretation of which was as follows: these inclusions are mixtures of 'normal' grains ('A' on figure 1), condensed from the same isotopic reservoir as all other solar system material, and grains ('B') with oxygen atoms constituted of ^{16}O only (no ^{17}O and no ^{18}O). There is no known process, operating in the solar region, capable of producing a sample free of ^{17}O and ^{18}O if it contained originally a mixture of the three stable isotopes. This implies that the grains with pure ^{16}O condensed prior to their being incorporated in the solar nebula, in an environment where no ^{17}O and no ^{18}O was present, and have been preserved

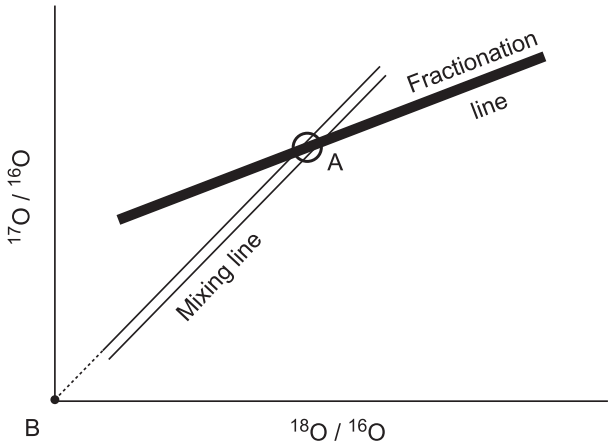

Figure 1. Isotropic diagram for oxygen. (After Clayton R N *et al* 1973 *Science* **182** 485–8 (© AAAS 1973).)

since. A major consequence was derived: the thermal evolution of the early solar system did not entirely erase the memory of presolar events; it is possible to identify grains with isotopic content indicating their presolar origin. Thus, the ^{16}O-rich phase could have been formed in a supernova envelope.

'Isotopic anomalies' refer to such abundance ratios which cannot be accounted for by solar system processes acting on samples accreted in an initial homogeneous reservoir of 'solar' composition. They are relics of stellar environments where presolar grains formed prior to their incorporation in the protosolar nebula, preserving their original isotopic composition until their accretion in solar system objects.

Another important isotopic anomaly, discovered soon after the pioneering O anomaly, is that of Mg. Mg has three stable isotopes, ^{24}Mg, ^{25}Mg and ^{26}Mg, with relative abundances 79%, 10% and 11%. In some carbonaceous chondrites, the Mg isotopes have been measured with a slight ^{26}Mg enrichment, found to be proportional to their $^{27}Al/^{24}Mg$ ratio. The interpretation is as follows: Al contains at present only one stable isotope, ^{27}Al. However, models of STELLAR EVOLUTION show that a number of stars, in particular SUPERNOVAE, also synthesize some ^{26}Al, an isotope which decays into ^{26}Mg with a half-life of 0.73 million years. The excess of ^{26}Mg in a grain would result from the *in situ* decay of ^{26}Al. The discovery of excess ^{26}Mg in a grain would thus indicate that it condensed in a gas containing both ^{27}Al and ^{26}Al.

The presence of ^{26}Al in the protosolar nebula would imply that the time between the synthesis of ^{26}Al, in a stellar environment, and its incorporation in the solar region and within the parent bodies of meteorites, is no more than a few million years: if not, all would have decayed, been homogenized in the gaseous nebula, and no anomalies would have been observed. In this very short time scale, considerably shorter than that of interstellar cloud collapse, a supernova would have exploded very

Dirac House, Temple Back, Bristol, BS1 6BE, UK

close to the protosolar nebula, loading it with unstable isotopes such as ^{26}Al. According to one model, this supernova, by its explosion, would have both driven the collapse of the presolar cloud, and injected some isotopes the decay of which could have served as the major energy source to initiate planetary evolution.

Actually, these pioneering and fundamental investigations triggered a huge development of experimental work, leading to the discovery of many more isotopic anomalies, sometimes identified at the level of individual micrometer-sized grains: indeed, one can state that interstellar grains have been isolated in the laboratory. Different classes of such presolar grains, extracted from all major types of carbonaceous chondrites, have been identified. They are all refractory enough in composition to have survived the inner solar system formation processes: so far, nanodiamonds (a few nm in size), SiC, graphite and corundum are the most numerous.

When measured at grain level, much larger isotopic anomalies are found, with respect to the first analyses, which were performed on mixtures of presolar and solar grains. Moreover, in addition to ^{26}Al, other short-lived isotopes have been discovered through excess of their daughter products: ^{41}K (decayed from ^{41}Ca, with a half-life of 0.1 million years) and ^{44}Ca (from ^{44}Ti, with a half-life of only 48 yr). Although ^{26}Al and ^{41}Ca could have been formed in different types of stars, such as supernovae, RED GIANT STARS (actually asymptotic giant branch) or WOLF–RAYET STARS, according to current nucleosynthesis models, ^{44}Ti seems to originate only from the explosive supernovae burning He: their carriers, when identified, are truly grains condensed in a supernova SN envelope, and preserved since.

These examples illustrate the potential that a systematic study of isotopic anomalies has to describe the geography of the presolar stellar environment and the history of solar system formation from the collapse of the interstellar cloud to the accretion of protoplanetary bodies. It emphasizes the major role that microscopic analyses of extraterrestrial samples can play in astrophysics.

Istituto di Radioastronomia, Bologna

The Istituto di Radioastronomia in Bologna is the main institute for research in radio astronomy in Italy. It conducts the study of the universe through radio waves and operates the Italian radio telescopes.

The institute, founded in 1970 from a previously existing university laboratory, is operated and funded by the Consiglio Nazionale delle Ricerche (CNR). The headquarters are located in Bologna, at the CNR Research Area, while the two observing stations are in Medicina (Bologna) and Noto (Siracusa, Sicily).

The staff consists of about 55 people, including astronomers, electronic engineers–physicists, software specialists, technical and administrative personnel. Additionally, 10 professors and researchers from the University of Bologna and the Observatory of Bologna, as well as many PhD students, post-doctorate fellows and undergraduate students, are affiliated with the institute.

The institute operates three radio telescopes. The 'Croce del Nord' radio telescope, in Medicina, is the largest transit instrument in the world, with its T-shaped arms of 564 m and 640 m, respectively. Since it was built, in the early 1960s, it has produced two important radio source catalogs (known as B2 and B3), with data on more than 30 000 objects.

The two identical single-dish antennas, each 32 m in diameter, located in Medicina and Noto, built in the 1980s, have been designed to work in conjunction with other foreign telescopes with the very long baseline interferometry technique (VLBI). They are members of European networks for both astronomy and geodynamics, and participate in observations with radio telescopes belonging to the American network (VLBA), to other countries in the world, and in space (HALCA). The institute is member of the JOINT INSTITUTE FOR VLBI IN EUROPE (JIVE).

A new large single-dish radio telescope, 64 m in diameter, is being built in Sardinia to increase the radio observing facilities, and to track interplanetary probes.

The research activity of the institute is the study of the physics of radio galaxies and quasars, stars, the interstellar medium and cosmology. The institute has gained a high level of expertise in the technological field related to the instrumentation required for large radio telescopes.

Italian Space Agency (ASI)

A government agency, founded in 1988, for the purpose of identifying, coordinating and managing Italian space programs. Under its five-year National Space Plan, ASI aims to promote, support and control the scientific, technological and commercial applications of space activities as well as to promote new technological capabilities in Italian aerospace industries.

Under ASI's leadership, Italy has been involved in a variety of space activities, including the International Space Station, Tethered Satellite, X-SAR (X-band Synthetic Aperture Radar) and Lageos (Laser-ranged geodetic satellite) programs. Cooperative scientific ventures include the Beppo-Sax x-ray satellite and the SAC-B satellite for the study of solar physics.

ASI also promotes and supports Italian scientific and industrial participation in EUROPEAN SPACE AGENCY programs, including Cassini–Huygens and Integral.

Ivory, Sir James (1765–1842)

Mathematician, born in Dundee, Scotland. After a business career he became professor of mathematics at the Royal Military College, Great Marlow (which became Sandhurst). He retired early because of ill-health and devoted himself to mathematical research, particularly as applied to astronomical problems such as the gravitational attraction of ellipsoids, the shape of self-gravitating rotating fluid bodies, the orbits of comets and atmospheric refraction.

James Clerk Maxwell Telescope

The 15 m diameter James Clark Maxwell Telescope (JCMT), the largest facility in the world designed specifically to operate in the submillimeter region of the spectrum, became operational in 1987. It is situated close to the summit of Mauna Kea, Hawaii, at an altitude of 4092 m.

The JCMT is operated by the Joint Astronomy Center in Hilo, Hawaii, on behalf of PPARC in the United Kingdom, the National Research Council of Canada and The Netherlands Organization for Scientific Research.

It is used to study a wide range of astronomical objects, including the Sun, comets, molecular clouds, galaxies, quasars and cosmic background radiation. On 11 July 1991, JCMT became the largest telescope ever to observe a total solar eclipse.

Its performance has been enhanced by the addition of SCUBA—the submillimeter common-user bolometer array—a camera and photometer which operates at millimeter and submillimeter wavelengths. SCUBA is cooled to 0.1 K and is the most sensitive and versatile of a new generation of imaging devices for the submillimeter region. It has two arrays of bolometric detectors. The long-wave array operates in the 750 and 850 μm atmospheric transmission windows, while the short-wave array is used for observations at 350 and 450 μm.

SCUBA, which was designed and constructed by the ROYAL OBSERVATORY IN EDINBURGH in collaboration with Queen Mary and Westfield College, London, began observations in May 1997. Since then, discoveries include detection of a ring of dust particles around Epsilon Eridani; a distant galaxy hidden in dust; and possible new solar systems in formation around Vega and Fomalhaut.

Jansky, Karl Guthe (1905–50)

American radio engineer, founder of radioastronomy, employed by Bell Telephone Laboratories to reduce noise ('static') in shortwave transatlantic radiotelephony. Using a crudely directional, rotating shortwave receiver array operating at 20.5 MHz and 45 kHz, and nicknamed the Merry-Go-Round, he noticed a continuous interference which changed its strength over the course of the day. At first, he believed the noise was caused by the Sun, but it transpired that the time of the peak was shifting over the course of the year, and a partial solar eclipse in 1932 did not reduce the signal. He realized that the noise had a period of a sidereal day, not a solar day, and was associated with the Milky Way, particularly the direction of Sagittarius, where the Milky Way was brightest. This static being outside the control of radio engineering, he moved on to other work. In 1973 the radioastronomical unit of flux density (10^{-26} watts per square meter per hertz) was named the *jansky* in his honor.

Janssen, Pierre Jules César (1824–1907)

Solar astronomer, born in Paris, founded and became head of the Astrophysical Observatory at Meudon, observed the bright line spectrum of a solar prominence in the total eclipse of 1868. The brightness of the emission lines suggested to him that they should be visible even outside an eclipse, and so they were (*see also* LOCKYER). Photographed the Sun (published in 1904 his *Atlas de Photographies Solaries*), discovered solar granulation (*see also* NASMYTH). 'Once celestial photography was realized, the French astronomers divided the Universe among themselves: Janssen took the Sun, Loewy and Puiseux the Moon, and the brothers HENRY the stars'. Established a solar observatory on Mont Blanc.

Japanese Astronomy

Astronomy in Japan has made rapid progress in the last two decades, placing Japan among the leaders in the field. Not only mm wave and x-ray astronomy since the 1980s but also the optical and infrared, gravitational wave and neutrino astronomy are now at the highest level in these fields. Astronomers are preparing ambitious future plans in both ground-based and space-borne astronomy, in spite of the many challenges that basic science in Japan faces.

Historical view of Japanese astronomy

Historically, astronomical research in Japan contributed little to the human understanding of the universe before World War II. In the Meiji era (1868–1912), Japan started introducing science and technology to catch up with the Western world. The government established faculties of engineering in universities as one of the earliest of such attempts in the world. However, most of the systematic and organized activities of basic sciences, including astronomy, started only after World War II.

The Norikura Solar Corona Observatory, started in 1950, and the OKAYAMA ASTROPHYSICAL OBSERVATORY with a 188 cm optical telescope (1960) of Tokyo Astronomical Observatory (TAO) and other observatories produced only a few observational results of the highest quality during the period of the 1950s to 1970s. However, these observatories established a foundation for observational astronomy in Japan. The TAO was then with the University of Tokyo and reorganized in 1988 as an interuniversity research institute, the NATIONAL ASTRONOMICAL OBSERVATORY, JAPAN (NAOJ). The progress in theoretical research in Japan, on the other hand, was remarkable in this period. The brilliant works by Chushiro Hayashi on the early universe, stellar structure and origin of the solar system, Yoshihide Kozai in celestial mechanics and Satio Hayakawa in high-energy astrophysics were among memorable contributions to the theoretical astronomy and astrophysics of humankind. In particular, the systematic works on the formation of stars and the solar system by C Hayashi and his group had built a firm foundation in the field.

In the 1960s small but extensive attempts started in radio, x-ray and infrared astronomy in Japan and grew rapidly throughout in the 1970s. It was in the 1980s that those efforts were rewarded with remarkable scientific and technological results.

Developments in radio astronomy

Solar radio observations in Japan started in the 1950s. The development of solar microwave interferometers by Haruo Tanaka was among the earliest in the field. The millimeter wave observations in Japan started in 1970 with a 6 m diameter telescope at Mitaka constructed by Kenji Akabane, Masaki Morimoto and their group. Their efforts led TAO to establish the NOBEYAMA RADIO OBSERVATORY (NRO) in 1982 with two top-level mm wave telescopes, the 45 m diameter telescope (the world's largest mm wave telescope until now) and the mm wave interferometer composed of five (a sixth added later) 10 m antennas with 570 m baseline. Norio Kaifu, Masato Ishiguro and their group led the construction and work on related developments such as high-precision antennas, acousto-optical radio spectrometer, Fourier correlation radio spectrometer, high-sensitivity SIS mixer receivers, closely cooperating with engineers from Japanese industries. Since its establishment the Nobeyama mm wave telescopes have been providing rich scientific results: detection of many exotic new molecules in interstellar clouds, protoplanetary disks, evidence of supermassive black holes in galactic nuclei, to name a few, making Japan one of the leading countries in radio astronomy.

Recently (1998) NRO succeeded in linking the 45 m telescope with the array of six 10 m diameter antennas for a seven-element mm wave interferometer called RAINBOW. It will be the most sensitive mm wave interferometer for the time before the planned international project ALMA (mentioned below). Another facility of NRO is a radioheliograph, completed in 1992 under the leadership of Shinzo Enome. The 84-element array of 80 cm diameter parabolas yields high-resolution radio images of the sun every second.

NRO and Mizusawa Astrogeodesy Observatory of NAOJ had started the VLBI observations with other Japanese institutes and organized a domestic VLBI network (J-Net). In 1997 the VLBI group led by Hisashi Hirabayashi and his group launched the world's first space VLBI satellite HARUKA as a collaboration among ISAS, NAOJ and overseas institutes. The launched 8 m diameter antenna is orbiting around the Earth to link with radio telescopes worldwide to form a 30 000 km aperture radio telescope (VSOP). It was an engineering and logistical challenge, and recently VSOP has produced clear images of many energetic galactic nuclei with extremely high resolution of 0.1–1 marcsec, approaching a linear size about 100 times that of supermassive black holes.

NRO, with its large mm wave telescopes, was the first top-level observational facility Japan had for astronomy. In the field of mm wave and sub-mm wave astronomy, university groups are now undertaking a number of small but excellent projects: a 4 m diameter mm wave telescope of Nagoya University (located at Las Campanas, Chile), a 60 cm CO molecular line mapping telescope of the University of Tokyo (La Silla, Chile), a 1.2 m remote-operation sub-mm carbon atom line survey telescope of the University of Tokyo (atop Mt Fuji) etc, yielding a large amount of observational data for specific scientific subjects.

Developments in x-ray astronomy

HAKUCHO, the first Japanese x-ray satellite, was launched in 1979 by the INSTITUTE OF SPACE AND ASTRONAUTICAL SCIENCE (ISAS) under the leadership of Minoru Oda. Subsequent series of ISAS x-ray satellites, TENMA (1983), GINGA (1989) and ASUKA (1993) under the leadership of Yasuo Tanaka and his group, with their rich scientific

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

results made Japanese x-ray astronomy one of the most productive in the world. Since the early identification of the x-ray source Sco-X1 with an evolved star using the balloon-borne x-ray telescope and the Okayama 188 cm telescope, efforts by ISAS and groups in universities in parallel with developments in space engineering have revealed the physics of dying stars and their energetic activities. ASUKA is a relatively small satellite (420 kg) but is actively continuing x-ray spectroscopic observations of various objects from star formation sites to clusters of galaxies in the very distant universe.

Solar x-ray observations have also been made by a successful collaboration of x-ray astronomy at ISAS and traditional solar physics at TAO/NAOJ. YOKO, launched in 1991 following the first Japanese solar x-ray satellite HINOTORI (1981), has been providing a tremendous number of x-ray images of the Sun and contributed to understanding of the physical process of energetic solar flares (project leaders: Yoshiaki Ogawara and Yutaka Uchida).

Recently ISAS developed the M-V rocket with a payload capability much higher than that of previous L-series rockets. The first launch of M-V was celebrated by the success of HARUKA/VSOP mentioned earlier. By using M-V, new astronomical projects such as Astro-E, IRIS and Solar-B are being promoted. Astro-E is a 1650 kg mass satellite with very high x-ray spectroscopic and imaging capabilities, to be launched in early 2000. Solar-B, a next-generation HINOTORI, is a 50 cm aperture optical solar telescope slated for 2004. IRIS is described below.

Developments in optical and IR astronomy

An 8.2 m aperture optical and IR telescope 'Subaru' atop Mauna Kea, Hawaii, started its test observations in early 1999 and will be opened to the astronomical community in late 2000. It is one of the new-generation telescopes with a large active-support primary mirror housed in a turbulence-suppressed cylindrical enclosure and has seven observational instruments that cover ultraviolet to mid-infrared ranges. Its high performance was demonstrated by stellar images with a full width at half-maximum of 0.2 arcsec and a number of spectacular scientific results through the test observation period. The construction of the SUBARU TELESCOPE, led by Keiichi Kodaira and later by Norio Kaifu and their group, started in 1991 as a 9 yr project of optical and IR astronomers of Japan.

Experience of Japanese optical astronomers has been mostly limited to the Okayama 188 cm telescope built in 1960 and the Kiso 105 cm Schmidt camera built in 1974. Infrared astronomers studied through the pioneering construction of the Agematsu 1 m IR telescope (1973) and observations with overseas telescopes led by Haruyuki Okuda and Shuji Sato. To build an engineering and technical basis for optical and infrared astronomy, the Advanced Technology Center was established at Mitaka campus of NAOJ headquarters. Close cooperation with university groups and industries was also organized for preparation, basic design and construction of the telescope and observing instruments. To overcome the lack of middle- to small-size modern telescopes and poor weather conditions in Japan, a 2 m IR telescope atop Haleakala, Hawaii, and a 1.2 m IR telescope in South Africa are being constructed by the University of Tokyo and by Nagoya University, respectively. Japan had never established a permanent governmental scientific facility abroad before the Subaru. NAOJ being a government organization, much effort was needed to overcome this hurdle and finally in 1997 the Subaru Telescope Facility was formally established in Big Island, Hawaii. Further progress toward internationalization is definitely needed for Japanese science and its future.

The Subaru Telescope, equipped with adaptive optics and versatile observational instruments, together with other new-generation telescopes such as VLT and GEMINI will embark on new frontiers including direct observations of extra-solar-system planets, detection of many small icy planetesimals orbiting beyond Pluto, observations of mysterious galactic nuclei, dark matter, distant clusters of galaxies and the youngest celestial bodies in the expanding universe.

Developments in other fields of astronomy and astrophysics

Recent major developments of experimental research in astrophysics in Japan include neutrino and gravitational wave astronomy. Kamiokande's neutrino detection from supernova SN1987A opened a new field of neutrino astrophysics. The Kamiokande (Kamioka, Japan) is a Cherenkov light detector initially built to detect proton decay (led by Masatoshi Koshiba and Yoji Totsuka). Because of the importance of neutrino observations, the Cosmic Ray Institute (CRI, University of Tokyo) constructed SUPER-KAMIOKANDE which is 10 times larger than Kamiokande with 50 kt of pure water in a tank 39 m in diameter and 41 m high, at the Kamioka site, 1 km underground. It confirmed the finite mass of the neutrino recently.

TAMA-300 is a Japanese pilot project in gravitational astronomy led by Yoshihide Kozai and joint groups of NAOJ and other institutes. The 300 m long L-shaped interferometer of TAMA-300 at Mitaka started operation in 1999. Its high sensitivity would make TAMA-300 able to detect gravitational waves for the first time, if they have fortunate events such as that for Kamiokande. As 3–4 km scale gravitational telescopes, LIGO of USA and VIRGO of France–Italy are to be commissioned within a few years; the Japanese gravitational telescope group is working on a further upgrade of TAMA-300.

AGASA, a large-aperture high-energy cosmic ray detector of CRI, is in operation at Akeno, Yamanashi, Japan. It aims to detect cosmic rays with extremely high energy ($>10^{20}$ eV) and identify their origin, which is still unknown.

Theoretical studies in Japan have kept their high level through the 1950s to the 1990s. The extensive studies of atmospheres of low-temperature stars by Takashi Tsuji,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the discovery of a mathematical solution for a rotating black hole by Akira Tominaga and Fumitaka Sato, the inflationary universe theory of Katsuhiko Sato and the theory of supernova explosions of Daiichiro Sugimoto and Kenichi Nomoto are examples of prominent contributions among many active theoretical studies in Japan. The availability of powerful computers is also providing a strong basis for theoretical work in Japan.

Future plans

Encouraged by this remarkable progress, Japanese astronomers are discussing their ambitious future facilities. An immediate project of Japanese ground-based astronomy is LMSA, which was originally planned as a Japanese large mm and sub-mm array consisting of 50 antennas each 10 m in diameter aimed at a wide range of study from planetary formation to cosmology. In 1994 LMSA was recognized as the next national project strongly supported by the astronomical community of Japan and the search for a site started in parallel in Chilean dry plateaux. The 4800 m elevation Pampa La Bola near the Atacama desert was selected as the best site. At present radio astronomers of Japan, USA and Europe are intensively discussing the consolidation of their similar projects: LMSA, MMA (USA) and LMA (Europe). The unified world array, ALMA, will be a challenging mm and sub-mm wave telescope with 100-element antennas and 10 km maximum baseline. Such an interferometer would enable humankind to obtain high-quality images of a variety of cosmic phenomena with spatial resolution of 0.01 arcsec. Compared with the current highest angular resolution of 0.1 arcsec of the Hubble Space Telescope and new-generation optical–IR telescopes, the images will be ten times sharper. The ALMA project will be an equally shared triple cooperation by Japan, USA and European countries with a total cost of the order of 1 billion dollars. Astronomers wish to start the operation before 2010.

VERA (VLBI Exploration of Radio Astrometry) is a national plan for high-accuracy radio measurements of distances to stars throughout the Galaxy to obtain a '3D map' of the Galaxy for the first time. Mizusawa and the NRO VLBI group of NAOJ, collaborating with the University of Kagoshima and others, started the construction of VERA toward its operation within a few years, with possibilities of cooperation with Asian countries. A sensitive gravitational wave telescope with 3 km baseline is being planned by groups at the University of Tokyo, NAOJ and other institutes. If coordinated with LIGO and VIRGO, it will provide information on the direction of gravitational wave sources. The Telescope Array project, a plan to extend the aperture for detecting extremely high-energy cosmic rays to 60 times that of AGASA, is being promoted by CRI under collaboration with the University of Utah, Australian groups and other universities.

Space-borne astronomy is another major frontier for the future of Japanese astronomy. In addition to the above-mentioned plans Astro-E and Solar-B, ISAS will launch the IR Imaging Surveyor (IRIS) in 2003 as the first Japanese infrared astronomy satellite. It is a survey-type 70 cm aperture telescope cooled by a hybrid system of liquid helium and a refrigerator with high-sensitivity imaging arrays covering near-IR to far-IR wavelengths. The enormous amount of high-quality IRIS images would also be effectively used by combining them with the IR observations from Subaru and equivalent ground-based IR telescopes.

Even larger astronomical satellites using HII rockets developed by the NATIONAL SPACE DEVELOPMENT AGENCY (NASDA) are being discussed. SELENE, a lunar orbiting explorer for lunar science, will be launched in 2004 as the first attempt. A second version of SELENE including pilot astronomical observations from the lunar surface is under consideration. As an extension of the HII program, astronomers have been discussing extensively various plans for a Japanese space telescope. The H2L2 project is one such plan to launch a 3–4 m aperture cooled telescope to a Lagrange point for IR observations. The future of Japanese astronomy requires close and flexible cooperation among institutions such as NAOJ, ISAS, NASDA and CRI and universities.

Challenges Japanese astronomy is facing

Recent activities in astronomy and astrophysics, backed by a high level of industrial technology and economic power, have enabled Japan to advance and achieve considerably in this field of science. However, Japanese astronomy is still facing difficult situations compared with those in the USA and European countries.

The numbers of Japanese astronomers and related institutes are extremely low. They are concentrated at two institutes (NAOJ and ISAS) and four departments at universities (Universities of Tokyo, Kyoto, Nagoya and Tohoku). The number of the INTERNATIONAL ASTRONOMICAL UNION (IAU) members per million population of Japan is only 2 and Japan is ranked roughly the 24th among the IAU member nations. Compared with about a dozen of the top-rank countries, Japan is struggling to achieve the same level of astronomy with 1/4–1/5 as many astronomers. Although astronomy is one of the most popular subjects among university students, the number of faculty positions for astronomy is very low even now and for the majority of students astronomy courses are not available. Such a situation partially comes from the inflexible system of Japanese universities.

The operation of scientific organizations is also a subject for improvement. Employment, budget and accounting are tightly controlled by governmental regulations, which are often restrictive for scientific activities. It also causes difficulties in international cooperation or activities in different cultures and traditions of various countries. In 1998 the Japanese Parliament formally proposed an extensive reform of governmental organizations including national institutes, such as NAOJ and ISAS, and universities. The proposed plan includes possible improvements with respect to the difficulties

Japanese basic science is facing. The future of Japanese astronomy toward the 21st century will depend greatly on the outcome of this innovation.

Jeans, Sir James Hopwood (1877–1946)

Astrophysicist, born in Ormskirk, Lancashire, England, worked at Cambridge, Princeton and Mount Wilson Observatory, and retired early to devote himself to research. Like CHANDRASEKHAR, Jeans worked on physical problems such as thermodynamics, applying the physics to astronomy, and writing lucid accounts of the whole field in books such as *The Dynamical Theory of Gases* (1904), *Theoretical Mechanics* (1906) and *Introduction to the Kinetic Theory of Gases* (1940). He was a brilliant broadcaster and writer of popular astronomy, including the best-selling *The Universe Around Us* (1929), published at the time when the scale of the expanding universe was becoming clear. He proposed a tidal theory for the creation of the solar system, based on the hypothesis of a close approach of a star to the Sun, which drew out a cigar of material, from which condensed the planets. The *Jeans length* is the characteristic size of a cloud of gas that will collapse under its own gravitational attraction, into, say, a cluster of stars or an individual star.

Jeffreys, Sir Harold (1891–1989)

Geophysicist and mathematician, born in Fatfield (near Durham), England, became Plumian professor at Cambridge, worked in many areas of science, including geophysics, where he studied earthquakes, and was the first to conclude from the waves that earthquakes initiated that the Earth has a liquid core. In astronomy he studied the outer planets, proposing models for their structures. He also studied the origin of the solar system.

Jet Propulsion Laboratory (JPL)

Located in Pasadena, California, JPL is a research, development and flight center operated for NASA by the California Institute of Technology. Its primary role is the exploration of the solar system through the use of robotic scientific spacecraft. JPL is also responsible to NASA for supporting research and advanced development related to flight projects.

JPL was founded in the 1930s when Caltech professor Theodore von Karman conducted pioneering research into rocket propulsion in the area adjacent to the current site. From 1944 onwards, the laboratory conducted research for the US Army. In November 1957 it was selected to design and build the first American satellite. Data from the 14 kg Explorer 1 led to the discovery of the Van Allen radiation belts.

On 3 December 1958, JPL was transferred to NASA. Since then, it has participated in almost all of the agency's planetary missions, including the Ranger and Surveyor lunar projects, the Mariner series, the Viking missions to Mars, the Voyager missions to the outer solar system, the Magellan Venus radar mapper, Galileo and Cassini. Current projects include the series of Mars Surveyor missions and proposals to send spacecraft to Europa and Pluto. JPL was also the US manager of the IRAS project to map the infrared sky.

In addition, JPL conducts studies of the Earth and its environment through satellites such as the Solar Mesosphere Explorer and Topex-Poseidon. A number of JPL experiments have been flown in the Shuttle payload bay, including several Shuttle imaging radar missions.

The laboratory also designs and operates NASA's Deep Space Network of antennas, which is used to communicate with lunar and interplanetary spacecraft.

Jodrell Bank Observatory

The Jodrell Bank Observatory is part of the University of Manchester and was founded by Bernard Lovell in December 1945. Its prime instrument, the 76 m, MK1 radio-telescope, was completed in 1957. It was given a major upgrade in 1971 and is now known as the Lovell Telescope. In its early years it pioneered the technique of long baseline interferometry which led to the discovery of quasars. A major use now is in the study of pulsars. In 1964 a second 26 × 32 m telescope, the MK2, was completed. Given a new surface in 1987, it is now used as one element of the MERLIN VLBI NATIONAL FACILITY. Observations by the Lovell and MK2 telescopes led to the discovery of the first gravitational lens, the double quasar, and their study continues to form a major part of the research efforts of the observatory. It also operates a number of telescopes, including the Very Small Array, on Mount Teide, Tenerife, to study fluctuations in the cosmic microwave background, and is building receivers for the Planck Surveyor spacecraft to extend this work in the future.

John of Holywood [known as Sacrobosco] (*c*. 1200)

Thirteenth century English translator who taught in Paris and provided students with a text-book on timekeeping, calculational methods and astronomy, the latter called *The Sphere*. A watered-down version of John of Seville's translation of *The Elements* by AL-FARGHANI, it was the long-term, best-selling, standard textbook in astronomy until the seventeenth century (it was published in 200 editions in the age of printing), even if it was barely adequate.

Johnson, Harold Lester (1921–80)

Astronomical photometrist, born in Denver, CO, he had a peripatetic career at American observatories such as Lick, Lowell, Washburn, Yerkes, McDonald, Tucson, Tonanzintla and the National Observatory, Mexico. At Lick, Gerard Kron inspired Johnson to use his knowledge of electronics acquired in wartime service to establish the fundamental limits of photoelectric photometry. Using the newly developed photomultiplier, he established that there was an error of a magnitude (factor of two) in the standard magnitudes of the stars in Selected Areas, then used as the basis to determine the distances of galaxies. He worked with W W MORGAN, to establish new photoelectrically measured standards, now known as the *Johnson–Morgan system*, or the U, B, V system, the *de facto* international standard of stellar (and later, galactic) photometry, used to construct color–magnitude diagrams of clusters and galaxies. Johnson demonstrated how star clusters of different ages have characteristically different color–magnitude diagrams and, in particular, how the turn-off point, where stars begin to depart from the zero-age main sequence can be used to estimate fairly precisely the ages of the clusters. Johnson's design of stellar photometer became the benchmark and it was replicated all around the world. In Texas, Johnson worked with Frank Low to extend the U, B, V system to the longer wavelengths of the near infrared, the R, I, J, K, L and N bands, providing a knowledge of the relative spectral distribution of star light from 0.3 to 10 microns, which he was able to calibrate to absolute flux. He was thus able to produce absolute energy curves for all sorts of important categories of stars: sub-dwarf stars, cepheids, M stars, carbon stars, infrared objects, even circumstellar shells and quasars. This important work provided the observational challenge for the theoretical modeling of a variety of astrophysical phenomena.

Joint Institute for Laboratory Astrophysics (JILA)

An institute run jointly by the University of Colorado and the US National Institutes for Standards and Technology (NIST)—formerly the National Bureau of Standards—since 1962. Located on the main campus of the University of Colorado at Boulder.

JILA was originally established to study gaseous interactions and precision measurements. It has subsequently expanded its mission to include the development of new measurement methods and standards, the improvement of industrial competitiveness, and the education of graduate students in technology.

JILA is a center for advanced theoretical and experimental research on subjects such as atomic interactions, spectroscopy, gravitational physics, radiative transfer and stellar interiors.

Examples of cutting-edge technologies developed in the JILA laboratories include the world's most precise laser, the coldest place in the universe, tools for manipulation of some of the smallest human-made objects in the world, ultrasensitive methods for vibration isolation, and state-of-the-art computer modeling of the Sun's turbulence.

Major areas of research include atomic and molecular interactions, new states of matter (Bose–Einstein condensates), cooling and trapping of matter, optical and laser physics, nonlinear optics and optical techniques, chemical physics, materials processing and semiconductor fabrication, nanometrology, precision measurement, gravitational physics, stellar atmospheres, interstellar astrophysics, solar physics and extragalactic astronomy.

Astrophysical research within JILA covers much of modern astrophysics—the interstellar medium, the Sun, stellar atmospheres and coronas, supernovae, x-ray stars, active galaxies, extragalactic physics and cosmology.

JILA astronomers are actively involved in a wide range of observational programs using leading ground-based facilities and major orbital observatories such as the Infrared Astronomical Satellite, the Hubble Space Telescope, the Compton Gamma-Ray Observatory, the Rossi X-Ray Timing Explorer and Chandra.

Traditional areas of interest include stellar atmospheres, and clusters of luminous stars, both in the galactic plane and in nearby starburst galaxies. Other major interests are the development of theoretical models to interpret the evolution of Supernova 1987A, and studies of cosmic x-ray sources. Extragalactic research activity focuses on the physics of interstellar matter, 'starburst' galaxies, infrared galaxies, the distribution of intergalactic gas, active galactic nuclei and quasars.

Joint Institute for VLBI in Europe

The Joint Institute for VLBI in Europe (JIVE) operates a purpose-built Data Processor for Very Long Baseline Interferometry (VLBI), comprehensively supporting the data analysis and processing requirements of the European VLBI Network (EVN). The EVN is an integrated array of radio telescopes spread throughout Europe and beyond, which conducts unique, high-resolution, radio astronomical observations of cosmic radio sources. JIVE was established in 1993 and is located in Dwingeloo, the Netherlands. JIVE is supported via national funding agencies. Its host institute is the Netherlands Foundation for Radio Astronomy.

JIVE has played a leading role in the construction and development of a new generation of VLBI correlator, the MkIV. The MkIV, produced its 'first fringes' in July 1997, was formally inaugurated in October 1998 and produced its first astronomical image in April 1999. It began production correlation in October 1999. Research interests of the staff include: faint radio sources, supernova remnants, pulsar astrometry, maser emission around stars, gravitational lenses, active galactic nuclei and VLBI techniques (incuding space VLBI and polarization VLBI).

Joy, Alfred Harrison (1882–1973)

Astrophysicist, staff member of Mount Wilson Observatory from 1915 for nearly 60 years, Joy worked on spectroscopy and the determination of the radial velocities of stars. He used the results to find the absolute magnitudes of Cepheid variable stars (as a contribution to the determination of the intergalactic distance scale), the distance of the galactic center and the Sun's rate of revolution about it. During the observational study of dark clouds he identified a population of irregular variable stars with chromospheric emission lines; these were named T Tauri stars after the bright prototype.

Julian Date (J.D.)

Also known as the Julian period, the number of days, and the fraction of a day, which have elapsed since noon on 1 January, 4713 BC. Thus 18.00 hours UT on 1 March 1980 corresponds to J.D. 2 4444 3000.25. For certain purposes, for example, when analyzing the frequency with which events occur over long periods of time, it is most convenient to use this system of dating. The Julian period was proposed by Joseph Justus Scaliger in 1583 and named by him after his father, Julius Caesar Scaliger.

Juno

The third asteroid to be discovered, by Karl Harding in 1804, and so designated (3) Juno. Its diameter is 268 km, and it orbits the Sun in the main asteroid belt at a mean distance of 2.67 AU (399 million km) in a period of 4.36 years; the orbital inclination is 13°, and the eccentricity 0.26. Juno rotates in 7.21 h. It is an S-type asteroid, with a reflectance spectrum indicating compositional similarities to stony-iron meteorites and ordinary chondrites; the albedo is quite high at 0.24.

Jupiter

JAt 5.2 AU from the Sun (table 1), Jupiter is the closest and the most massive of the GIANT PLANETS, which extend in the outer solar system up to heliocentric distances of 30 AU. Its mass amounts to 318 terrestrial masses, and its diameter is 11 times the terrestrial one (table 2). Like the other giant planets, Jupiter has a low density (1.31 g cm^{-3}) which reflects its chemical composition, mostly dominated by hydrogen and helium. Jupiter has a fast rotation around its polar axis (9 h 55 min) which induces a characteristic structure of belts and zones, parallel to the equator.

Table 1. Orbital characteristics of Jupiter.

Semi-major axis of the orbit	5.202 AU
Eccentricity	0.048
Inclination over the ecliptic	1°18′ 28″
Sidereal period	11 yr 314.84 days
Mean orbital velocity	13.06 km s^{-1}

Table 2. Physical characteristics of Jupiter.

Equatorial diameter	142 796 km
Equatorial diameter relative to the Earth	11.19
Polar diameter	133 540 km
Flattening	0.062
Mass relative to the Earth	317.9
Mean density	1.31 g cm^{-3}
Surface gravity (at P = 1 bar)	24.8 m s^{-2}
Surface gravity relative to Earth	2.64
Escape velocity	59.64 km s^{-1}
Sidereal rotation	9 h 50 min to 9 h 56 min
Inclination of equator versus orbital plane	3° 04′
Albedo	0.45
Main atmospheric composition	H_2 (89%) He (11%) CH_4 (0.2%)

Jupiter has a ring system and many satellites (see JUPITR: RINGS, JUPITER: SATELLITES). Its ring is very tenuous; the planet is surrounded by 39 satellites (discovered to date), including the four main ones known as the Galilean satellites (see figure 1). Another characteristic of Jupiter is its magnetosphere, more massive than those of the other giant planets, and comparable in some regards to the terrestrial magnetosphere (see JUPITER: MAGNETOSPHERE, MAGNETOSPHERE OF EARTH).

Our knowledge of Jupiter started with the beginning of telescopic observations, more than three centuries ago. Over the last three decades, considerable progress has come from space exploration, but also from the on-going technological developments of ground-based astronomy.

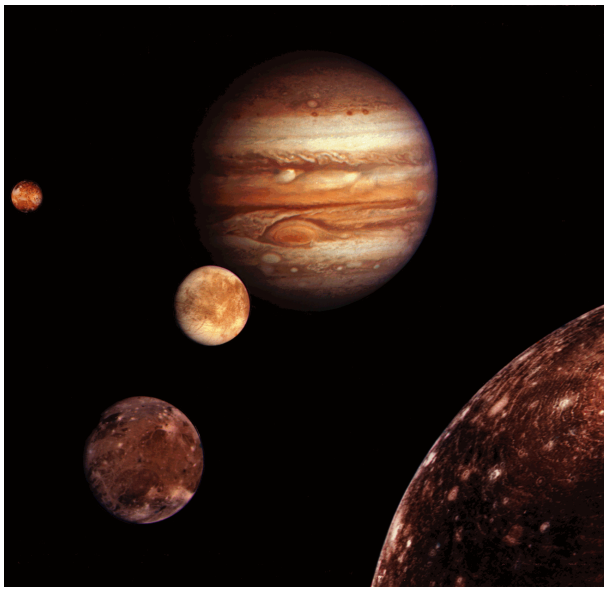

Figure 1. Jupiter and the four Galilean satellites. This picture shows a combination of images from the Voyager 1 spacecraft as it encountered the Jovian system in March 1979. The Great Red Spot appears in the southern hemisphere of the Jovian disk. Io is the red satellite on the left, Europa is the white satellite at the center, Ganymede is left and Callisto is on the front. Jupiter and the four Galilean satellites were most probably formed together; this formation scenario is needed to account for the near-circular orbits of the Galilean satellites, all very close to the equatorial plane of Jupiter.

The early observations

As one of the brightest objects in the sky (visual magnitude of –2.6 and angular diameter up to 44" at opposition), Jupiter has been known from antiquity. Its astronomical observation started almost four centuries ago with the appearance of the first refractors and telescopes. Galileo is believed to be the first astronomer to have discovered, in 1610, the four large satellites orbiting the planet, known since that time as the Galilean satellites. A few decades later, the band and zone structure was identified; in 1664, Robert Hooke discovered the GREAT RED SPOT (GRS) which was then extensively studied by Cassini. A continuous monitoring of the planet has taken place since that time, showing in particular the stability of the GRS for over three centuries.

The development of spectroscopy, early in the twentieth century, allowed the first detection of some atmospheric compounds (methane and ammonia were discovered by Wildt in 1932), but hydrogen, the most abundant atmospheric constituent, although strongly suspected on theoretical bases, was not identified until 1960 (detection by Kiess and colleagues); helium, the second gas in terms of abundance, remained undetected until the space era. Since the 1970s, however, the development of ground-based infrared spectroscopy has led to the detection of more than a dozen atmospheric constituents, including

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

phosphine, germane, water vapour, ethane, acetylene and various isotopic species (see JUPITER: ATMOSPHERE). In July 1994, with the collision of comet Shoemaker–Levy–9 with Jupiter, astronomers were given an exceptional opportunity to study in real time the response of a planetary atmosphere to a major meteoritic impact. The set of collisions induced strong stratospheric heating and the formation of new species, some of them remaining visible for the following two years (see SHOEMAKER–LEVY 9–JUPITER COLLISION).

Another major result of the ground-based exploration of Jupiter was the early discovery, in the 1950s, of a strong radio emission, in the decimetric and decametric range. This non-thermal emission was interpreted as the signature of a strong magnetic field. The decimetric emission was interpreted as synchrotron radiation of electrons orbiting along the radiation belts of Jupiter; this radiation is modulated by the motion of Jupiter's inner Galilean satellite IO. The decametric radiation, characterized by sporadic emissions, appears to be due to magnetic outbursts and storms (see figure 2).

The space exploration

The first step in the space exploration of the Jovian system was its encounter by the Pioneer 10 and 11 spacecraft, in 1973 and 1974 respectively. The PIONEER MISSIONS provided the first high-resolution images of the atmospheric structure, and an *in situ* investigation of its magnetosphere. But the space era really started in 1979 when the two VOYAGER spacecraft encountered the planet. Not only did the cameras reveal an unexpected variety and complexity in the cloud structures and their dynamics, but they also discovered the ring system of Jupiter, active volcanoes on Io (providing the first evidence for active volcanism outside the Earth), and a great diversity in the surfaces of the other Galilean satellites. The Voyager spacecraft also discovered other smaller satellites, bringing the list of known satellites to 16.

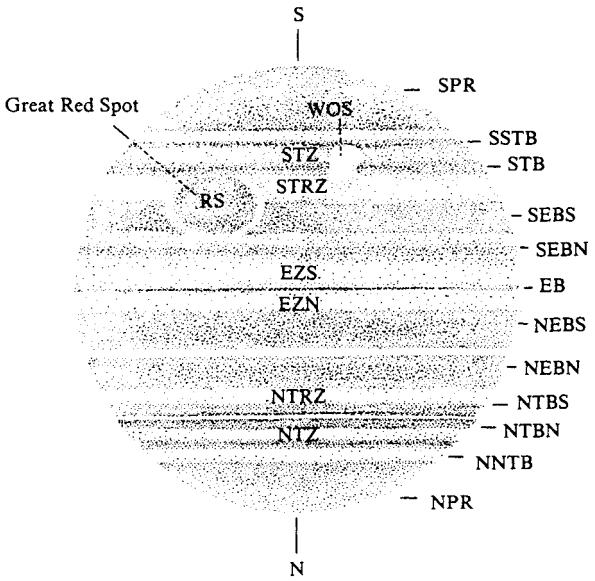

Figure 2. Belts and zones in Jupiter. Their nomenclature is given in table 3. Temperature measurements recorded in the infrared range have shown that the belts exhibit higher temperatures than the zones. It is generally believed that zones are regions of ascending motion on top of which clouds form, while the belts are are cloud-free regions of descending currents. This analysis has been confirmed by the Galileo probe, which has entered a dry and cloud-free region in one of the hot spots of the NEB; however, Galileo observations have also demonstated that the Jovian circulation is more complex by far than this simple scheme, with considerable small-scale structure.

The GALILEO MISSION, launched in 1989, arrived at Jupiter on December 7, 1995. Upon its arrival, a descent probe was sent into the Jovian atmosphere and provided data down to an atmospheric level at a pressure of 22 bars. Since that time, the Galileo orbiter has extensively monitored the Jovian atmosphere and the Galilean satellites, providing a huge amount of information about the atmospheric structure, cloud evolution and dynamics, the satellite surfaces and the magnetospheric environment. In particular, the analysis of images of EUROPA's surface suggests a possible ocean of water below the water ice crust of Europa. In order to study more deeply the surface and subsurface of Europa, the Galileo mission has been extended into the Galileo Europa Mission (GEM).

The CASSINI spacecraft, en route to Saturn, flew past Jupiter in 2000. Cassini observed Jupiter from 1 October 2000 to 31 March 2001, making its closest approach on 30 December 2000, at a distance of about 9.7 million kilometers (6 million miles). During the fly-by, new observations of Jupiter, its satellites and environs were made by Cassini, Galileo, the Hubble Space Telescope, the Chandra X-ray Observatory and Earth-based radio and optical telescopes.

Composition and structure

Why is Jupiter mostly composed of light elements? Its low density can be explained in the light of the model which accounts for the formation of the two classes of planets, the telluric ones and the giants. It is now generally believed that the solar system was formed from a protoplanetary disk which encountered the gravitational collapse of an unstable interstellar cloud submitted to accelerating rotation. The central part of the disk accreted into the proto-Sun, while planets were formed from the accretion of planetesimals made out of the disk matter.

At small heliocentric distances (R_h<2 AU), the temperature was probably such that only metals and silicates could condense, giving birth to the cores of the telluric planets. However, at larger heliocentric distances, many more abundant molecules, like CO_2, H_2O, CH_4 or NH_3, were present in solid form. These ices, added to the

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

metals and silicates, contributed to solid cores which could be at least ten times more massive than the Earth. At this stage, the gravitational field of these cores became sufficient to accrete by gravitational collapse the surrounding gaseous nebula, mostly formed of hydrogen (75%) and helium (25%) as is all interstellar and cosmic material. As a result, the atmosphere of the giant planets reflects, to first order, the chemical composition of the primordial nebula which gave birth to the SOLAR SYSTEM, 4.5 billion years ago.

Because they were at further distances from the Sun, in a less dense part of the protoplanetary disk, the accretion process of the core probably took more time for URANUS and NEPTUNE than for Jupiter and Saturn. The accretion phase of the surrounding nebula may then have taken place at a time when the primordial gas was already partly swept away in the T-Tauri phase of the young Sun, and less primordial gas may have been available. This scenario could explain why Uranus and Neptune have a very large fraction of their mass in their central core (probably 60 to 80%) as compared with Jupiter and Saturn (3 to 15%).

For this reason, Jupiter, the most massive and gaseous of all giant planets, is a precious witness to the early stages of solar system history. The study of its elemental and isotopic composition can provide key diagnostics on the chemical composition of the primordial solar nebula in the outer solar system at the time of the planets' formation. The abundance of deuterium and helium are of special interest for this study. In addition, a comparative analysis of elemental and isotopic abundances on all giant planets is a valuable tool for understanding the formation and evolutionary processes of these objects.

From the similarity of the chemical composition of Jupiter with cosmic abundances, it is possible to see some analogy between the giant planet and the smallest stars; the main difference, however, is that the mass of Jupiter is only 0.1% of the solar mass, while the critical mass for star formation is about 8%. Below this threshold, the internal temperature is not sufficient to give rise to thermonuclear reactions through which hydrogen is converted into helium and later into other heavier elements. Jupiter, in this view, could be considered as a low-mass example of the class of 'brown dwarfs', those hypothetical cold objects which are currently extensively searched for, as they might contribute to a significant part of the hidden mass of the Universe.

As hydrogen is the main element of the Jovian atmosphere, most of the constituents are in reduced form: CH_4, NH_3, PH_3, GeH_4, AsH_3 and H_2O. H_2S, which had remained undetected from spectroscopic remote sensing observations, has been analysed by the mass spectrometer of the Galileo probe. Another class contains the hydrocarbons which are formed from the photodissociation of methane by the solar UV radiation (C_2H_2, C_2H_6…). A third class contains the isotopic species: HD, $^{13}CH_4$, CH_3D, $^{12}C^{13}CH_2$, $^{15}NH_3$…. The ISO satellite has recently discovered the presence of gaseous H_2O and CO_2 in the stratosphere of Jupiter, as well as in those of the other giant planets and TITAN this oxygen source might originate from an interplanetary meteoritic flux or also partly from the giant planets' icy satellites and rings.

For over two decades, there have been repeated attempts, both from ground-based and space observations, to determine the relative abundances of elements which are expected to be most abundant after hydrogen and helium, namely C, O, N, P and S. After many uncertain and sometimes contradictory results, the Galileo probe has given us important new information on the chemical composition of the lower atmosphere, at pressure levels up to 20 bars. From the present state of knowledge, it is now believed that in the deep troposphere, below the levels where condensation may take place, there is an enrichment in carbon, sulfur, phosphorus and nitrogen with respect to the solar value (there is no definite result on a possible oxygen enrichment, because the region entered by the Galileo probe was especially dry, and not representative of the whole planet). This enrichment is most likely due to the ices contained in the core, which were probably mixed in the Jovian atmosphere in the heating phase generated by the collapse of the surrounding nebula around the Jovian core. It can be seen that the scenario of formation of the giant planets mentioned above, called the 'nucleation scenario', receives strong support from the measurements of elemental abundances. It is also expected that the enrichment should increase with heliocentric distance as the relative mass of the core increases for the more distant giant planets. This is indeed the case for methane, strongly enriched on Uranus and Neptune.

The thermal vertical profile of Jupiter is characterized by two main regions: in the troposphere, down to the interior, the heat is transferred by convection (as in stars) and the temperature decreases as the altitude increases, following an adiabatic gradient. The temperature reaches a minimum of 110 K at the tropopause, where the pressure level is about 100 mbar. Above the tropopause, the temperature increases again with height, due to the absorption of the solar UV and near-IR flux by methane and aerosols; this is the statosphere where the energy is transferred by radiation.

The region sounded in the visible and infrared range is mainly the upper troposphere and the lower stratosphere, at pressures ranging mostly between a few bars and about 1 mbar; the UV radiation probes the Jovian stratosphere. In addition, the upper stratosphere is also probed at specific infrared wavelengths corresponding to ion or molecular transitions, where thermal emission probes the microbar pressure level. Some of the atmos-

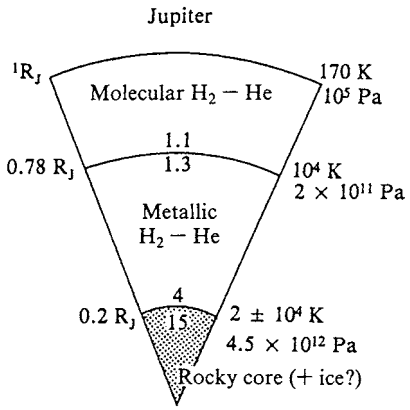

Figure 3. Model of the internal structure of Jupiter (after Stevenson 1982). Jupiter is believed to have formed from the gravitational collapse of primordial gas (mostly composed of hydrogen and helium) on a central core made of rock and ice having about 10 to 15 terrestrial masses, at an early point in the history of the solar system. The internal temperature may then have reached 10^5 K. The heat accumulated during the accretion phase has been continuously re-radiated to space since the origin in a slow contracting phase. The central temperature today is believed to be 23 000 K. Most of Jupiter's interior is probably made of convective liquid metallic hydrogen. There may be no definite transition between the metallic hydrogen and the molecular hydrogen which overlays it.

pheric species condense in the upper troposphere: from thermochemical calculations, NH_3 is expected to condense at around 0.5 bar, and NH_4SH and H_2O at lower levels; the NH_3 cloud is believed to be responsible for the white color of the planet observed in the visible range, especially in the zones.

The internal structure of Jupiter is only known from indirect measurements and from theoretical modeling (see figure 3). The known parameters are the radius, mass and density, and the gravitational moments have been measured by the Voyager spacecrafts. Another important parameter is the internal energy of the planet, which was first discovered by Low and his colleagues from ground-based infrared measurements, and was later more accurately measured by the Voyager spacecraft. Based on these observational constraints and on theoretical models, it is possible to estimate the pressure (50 to 100 Mbars) and the temperature (23 000 K) at the center of the planet. It is currently believed that the interior consists of a solid nucleus of about 10 to 15 terrestrial masses, probably made of rocks and metals at the center, surrounded by a convective ocean of metallic hydrogen, where the magnetic field of Jupiter is believed to be generated. It is likely that helium differentiation takes place in the liquid hydrogen, with helium droplets falling toward the center, as in the case of Saturn. The released energy probably contributes, with the planet's contraction, to the observed internal energy of Jupiter. Above the metallic hydrogen ocean lies the molecular hydrogen convective envelope. A powerful method for learning about the internal structure of Jupiter will be the measurement of the oscillation modes of the planet, as these oscillations are expected to probe its deep interior.

Dynamics

The internal energy source of Jupiter has important consequences for Jovian dynamics. The main features are the belt and zone structures induced by the fast rotation of a convective sphere (table 3). Spacecraft observations have shown that the zones are colder and cloudier than the belts; they are believed to be regions of ascending motion, while the belts, which are drier, are regions of subsidence. The Galileo probe, in December 1995, entered one of these dry regions, so that the atmospheric structure and composition retrieved from the probe data are probably not representative of the whole planet. Moreover, high-resolution images and spectroscopic observations from the Galileo orbiter have demonstrated that the Jovian circulation is much more complex than this simple zone/belt scheme, and that vertical motions also exist on a small scale.

Table 3. Nomenclature of the Jovian belts and zones.

Designation	*Definition*	*Approximate latitude (degrees)*
NPR	North polar region	47–90
NNTB	North-north temperate belt	43
NTZ	North temperate zone	35
NTBn	North temperate belt (northern component)	30
NTBs	North temperate belt (southern component)	23
NTRZ	North tropical zone	15–20
NEBn	North equatorial belt (northern component)	14
NEBs	North equatorial belt (southern component)	10
EZn	Equatorial zone (northern component)	+3
EB	Equatorial belt	0
EZs	Equatorial zone (southern component)	–3
SEBn	South equatorial belt (northern component)	–10
SEBs	South equatorial belt (southern component)	–19
GRS	Great Red Spot	–22
STRZ	South tropical zone	–25
STB	South temperate belt	–29
STZ	South temperate zone	–37
WOS	White oval south	–35, –37
SSTB	South-south temperate belt	-41
SPR	South polar region	45–90

The Coriolis forces induce zonal winds of opposite direction north and south of each zone, generating multiple time-variable eddies. The biggest structure is the GRS, in the southern hemisphere, which is currently interpreted as a giant anticyclonic structure, i.e. a column of ascending motion; however, its stability for over three centuries is not understood at present. There are many other smaller eddies which were first observed with the Voyager cameras; these features have been monitored with the HST and with the camera of the Galileo orbiter. Most of them evolve rapidly with a time-scale of a few months.

If the white color of the zones can be reasonably interpreted as NH_3 ice, the composition of the clouds and/or gases present in the eddies is still a puzzle, especially in the case of the GRS. Its red color suggests the presence of phosphorus or sulfur compounds, but their chemical composition has not been identified yet.

The Jovian magnetosphere

Jupiter has at least three factors which favor the presence of a large magnetosphere: the presence of a liquid metallic interior, the fastest rotation and the largest size of all planets. Consequently, Jupiter has the largest magnetosphere in the solar system.

The Jovian magnetic field is believed to be generated by the dynamo effect within the liquid metallic hydrogen ocean which extends in Jupiter's interior below about 0.75 Jovian radii down to the central core. Following the first identification from ground-based radio measurements, the planetary magnetic field was explored by Pioneer 11 in 1974, then the two Voyager spacecraft in 1979. The dipole moment, tilted by 10° with regard to the rotation axis, is almost 20 000 times the terrestrial value; the intensity of the Jovian magnetic field at the equator is about 10 times the terrestrial value at the Earth's surface; it is even about three times higher at the Jovian poles than at the equator.

Due to the strong magnetic field, the fast rotation of the planet and the large heliocentric distance of the planet, the Jovian magnetosphere is extremely extended. Its structure, however, shows considerable analogy with the Earth's magnetosphere. It is characterized, in the sunward direction, by the presence of a shockwave, a magnetopause and a magnetosheath. A major difference from the Earth configuration is the presence of Io, the orbit of which crosses the Jovian radiation belts (see MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS). In the antisolar direction, the magnetic tail extends almost up to Saturn's orbit.

Rings and satellites

It has been believed for centuries that Saturn was the only giaant planet with a ring system In 1977, however, nine rings were discovered around Uranus from an airborne stellar occultation experiment. Then, in 1979, a ring was fortuitously found around Jupiter on Voyager 1 images, very close to the planet. Improved images were obtained a few months later using the Voyager 2 camera. Finally, in 1989, Voyager 2 confirmed the existence of a ring system around Neptune, also inferred from previous ground-based occultation experiments.

The Jovian ring is located in the planet's equatorial plane. The first ring extends over about 5700 km, and its outer edge lies at about 57 000 km from the planet's limb. Like Saturn's ring, the ring is very thin, as its width does not exceed 1 km. This first ring is followed by another brighter one, which extends over 800 km, itself followed by a third ring, darker and very tenuous, made of micrometer-size particles, which extends up to three Jovian radii. The rings are likely to be made of dust and water ice.

The satellites of Jupiter fall into three categories (table 4): the four big Galilean satellites, known since their discovery by Galileo in 1610, the four inner satellites Metis, Adrastea, Amalthea and Thebe, and the high outer satellites. Of the inner satellites, only Amathea was known prior to the Voyager exploration. They are all smaller than 100 km in diameter and irregular in shape, and the two closest to Jupiter, Metis and Adrastea, are associated with its ring system. The inner satellites, as well as the Galileans, are believed to have accreted from a protoplanetary disk surrounding the protoplanet Jupiter. In contrast the outer satellites, which all have orbits with eccentricities higher than 0.1 and inclinations larger than 20°, are most likely captured bodies, originating from comets or from the family of Trojan asteroids.

Table 4. The satellites of Jupiter.

Name	*Sidereal orb. period (days)*	*Semi-major axis (plan. rad.)*	*Diameter (km)*	*Density ($g\ cm^{-3}$)*
Metis	0.294	1.80	(40)	?
Adrastea	0.297	1.80	(30)	?
Amalthea	0.489	2.52	270–170–150	?
Thebe	0.678	3.11	(80)	?
Io	1.769	5.78	3632	3.53
Europa	3.551	9.40	3138	2.97
Ganymede	7.155	14.99	5262	1.94
Callisto	16.689	26.33	4800	1.86
Leda	240.0	156.0	2–14	?
Himalia	250.6	159.8	180	?
Lysithea	260.0	163.2	6–32	?
Elara	260.1	163.4	80	?
Ananke	631(r)	290.0	6–28	?
Carme	692(r)	313.0	8–40	?
Pasiphae	735(r)	326.3	8–46	?
Sinope	758(r)	332.0	6–36	?

(r) = retrograde.

The Galilean satellites

Discovered by Galileo in 1610, the four Galilean satellites have played an important role in the history of astronomy. In 1675, the Danish astronomer Ole Rømer used their mutual eclipses and occultations, at conjunction and opposition, to show that light had a finite speed and to estimate its velocity.

Together with Jupiter and its ring system, the four Galilean satellites represent a sort of replica of the solar system, on a smaller scale: they all have direct, nearly circular orbits, very close to the Jovian equatorial plane; their densities decrease as their distance to Jupiter increases because, as in the case of the solar system, the lightest elements of the closest satellites have evaporated due to heating from Jupiter. The study of the four Galilean satellites has greatly benefited from the Galileo mission, devoted to their in-depth exploration until early 2000.

While the three other Galilean satellites are covered with water ice, Io, Jupiter's innermost Galilean satellite is covered with sulfur and/or sulfur compounds which are responsible for its reddish color. One of the most important discoveries of Voyager was the first evidence for active volcanism on Io. The origin of this volcanism is internal heating caused by frictional dissipation of tidal energy generated by its orbital resonance with Europa. Its high density (3.5 g cm^{-3}) suggests an interior mostly made of silicates, as in the case of the Moon. Io has a very tenuous stable atmosphere of SO_2, with a surface pressure in the range of 4–30 nbars. In addition, material removed from Io's surface (atoms of H, O, S, Na, K) is sent to space and supplies a torus surrounding Io's orbit and containing neutral atoms and ions.

Europa, the smallest Galilean satellite, shows a surface of pure water ice, with very few topographic features. What is remarkable on this surface is the net of linear structures which covers the surface. High-resolution images of Galileo suggest that these structures could be due to the presence of liquid water below the icy crust, which would occasionally flow out as a geyser. If confirmed, Europa would be the only object apart from Earth to have an ocean of liquid water at present. Below this ocean, the interior of Europa is likely to contain silicates.

GANYMEDE, the third Galilean satellite, is the largest satellite of the solar system; it is even larger than MERCURY and PLUTO. The surface of Ganymede is dark, which implies, together with its density (1.94 g cm^{-3}), that the satellite is composed of water ice and silicates in roughly equal amounts. A major result from Galileo was the discovery of a magnetic field around Ganymede; its origin is currently unclear.

Finally, CALLISTO, Jupiter's outermost Galilean satellite, shows a heavily cratered surface, much older than the others. Being farther from Jupiter, Callisto probably benefited from a weaker internal energy source, and its surface has thus remained unchanged over its history.

Jupiter Atmosphere

In many aspects, JUPITER is intermediate between a planet and a star. As a star, it is mainly composed of hydrogen and helium, has an internal source of energy (although not from nuclear reactions) and has a convective interior (at least in part). As a planet, it experiences cold temperatures, receives energy from solar radiation in its atmosphere and shows a cloud structure with meteorological features different from but not dissimilar to those of the telluric planets. The scientific questions raised by investigations of Jupiter belong equally to both sides, stellar and planetary physics. On the planetary side, the comprehension of the meteorology of Jupiter remains a difficult challenge for atmospheric dynamics, for example. On the stellar side, the recent discovery of brown dwarfs, and extrasolar planets of comparable size (or even greater) (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS) shed new light on Jupiter, as the closest object to Earth in a new category of astronomical objects, which remain to be classified. Jupiter is not only the largest planet of the solar system, it is now viewed as a small object in the class of the extrasolar giant planets and brown dwarfs. It is at the bottom line of a classification starting from the gaseous planets, to the brown dwarfs and up to the stars themselves. However, contrary to the far and inaccessible stars, Jupiter is close enough to be studied by interplanetary probes. The exploration of Jupiter environment started with the PIONEER 10 and 11 spacecraft in the years 1973–4, followed by VOYAGER 1 and 2 in 1979–80. Jupiter also received a visit from the Ulysses spacecraft en route to its polar orbit around the Sun, in 1992 (see SOLAR WIND: ULYSSES). Ulysses made measurements of some plasma properties, density and temperature of the electrons, for the first time outside the equatorial plane. Then, in 1995, the Galileo probe observations gave the first *in situ* measurements in a giant planet's atmosphere, followed by remote sensing observations by the Galileo orbiter after 1995 (see GALILEO MISSION TO JUPITER). Our knowledge of Jupiter has been deeply modified by these space missions, together with the continued observations from ground-based telescopes with uninterrupted improvement in sensitivity and accuracy. Even if many unknowns remain on the giant planet, even if the reddish color of some of its clouds remains a mystery, our knowledge of Jupiter is now infinitely more detailed than before space exploration. The composition, cloud structure and temperature structure have been measured or inferred, at least in general guidelines; the circulation is accurately characterized, even if not understood globally. Also, ideas on the formation of Jupiter are now more precise, even if, as usual, the new findings have also opened new and difficult questions for investigators of the 21st century.

Meteorology

Even after the close observation of several space missions, the meteorology of Jupiter still keeps many of its mysteries. Decades of painstaking telescopic observations by amateur and professional astronomers gave a first general description of Jupiter's wind system (figure 1): large zonal winds are permanently present and roughly correlated with the banded structure of the clouds (zones and belts, being the generic names of these white and dark bands). Jets alternate in prograde and retrograde direction, producing the so-called differential rotation of the planet. The equator of Jupiter makes a full rotation in 9 h 50 min 30 s (defining system I of longitude) while the midlatitudes rotate in 9 h 55 min 40 s (system II). A more accurate system of rotation is now used, in relation to the periodicity of the radio emission of Jupiter, itself related to the magnetic field. In system III, the sideral period of rotation is 9 h 55 min 30 s, and the winds, measured with reference to this system of longitude, reach about 120 m s^{-1} at the cloud top at the equator (prograde). The differential rotation is very stable temporally: only subtle variations are seen between Voyager and Galileo in the wind profiles, mostly in the strongest jets, but the latitudes of the jets and their amplitude remain essentially constant. The depth of the wind system has long been debated, some astronomers favoring models with a thin atmospheric layer where winds are produced by the solar energy deposition close to the clouds' level, while others predicted a thick meteorology, with differential rotation extending into the interior, generated by the deep convection. The Galileo probe, sounding Jupiter at 6.57°N latitude, has observed strong winds down to the 22 bar

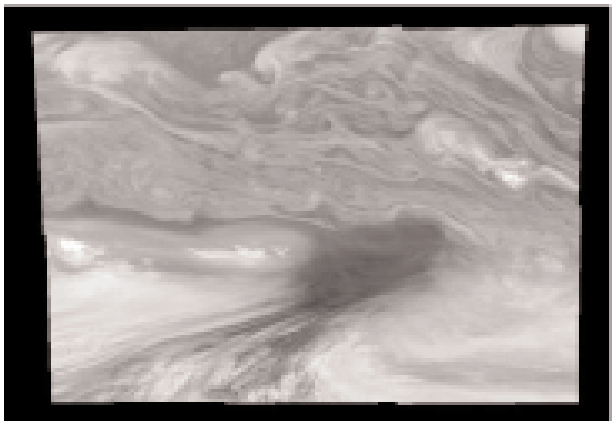

Figure 2. A hot spot of Jupiter, as observed from the Galileo Orbiter on 17 December 1996.

level, well below the upper meteorological layer: winds increase from 120 m s^{-1} at the cloud level (1 bar level) to about 170 m s^{-1} at 5 bar, and remain constant below. This observation seems to favor the models where the winds are supported by internal energy transport more than models with solar energy deposition, although the debate is still open, internal motions being possibly also driven by the deposition of energy in a thin upper boundary layer in other more recent models.

Another peculiarity of Jupiter's atmosphere is the morphology of its numerous spots. Among them, the most famous is the GREAT RED SPOT (GRS), observed during more than three centuries, since its discovery by Hooke in 1664. It is a large anticyclonic oval vortex, about 20 000 km wide in the longitudinal direction, located in the southern tropical zone. New observations from Galileo have shown that the center of the GRS is rotating slower than its boundary, with even an apparent counterrotation of the core of the GRS. The cloud structure inside the GRS, deciphered by Galileo's remote sensing instruments, shows a spiraling structure, with higher-altitude clouds at the core. Many numerical models of the GRS have been developed: the formation of large vortices is a general property often observed in turbulent rotating flows. In a recent model of turbulence, Sommeria *et al* (1988) explain the stability of large vortices by a statistical formulation of the turbulence, defining an analogy of the thermodynamics for the turbulence. This model is related to modern developments aimed at a global understanding of turbulence, one of the most difficult problems in physics. The observations of Jupiter therefore help to constrain such models, thanks to the observations of turbulent flows at scales inaccessible to laboratory experiments.

There are many other interesting features in the Jovian meteorology such as the White Oval Spots (WOSs), three anticyclonic ovals, first observed in 1938 in the South Temperate Belt. In 1998 and again in 2000, as their separation was at a minimum, two of the WOSs merged into one, leaving only one WOS, a unique event in the meteorological history of Jupiter. Galileo has measured the wind structure inside the WOSs, before and after the event, as well as the cyclonic structure between two oval spots. The most famous meteorological features in recent Jovian physics are the North Equatorial Belt Hot Spots (figure 2), because the Galileo probe unexpectedly descended directly inside one of them. These so-called 'hot spots' are regions of low cloud opacity, where thermal emission from the deeper layers is directly transmitted, which give these spots a larger flux in thermal emission at wavelengths where the atmospheric opacity is small enough for deeper soundings than in the cloud layers, such as the 5 μm spectral range. Hot spots have been observed from the ground since the beginning of infrared astronomy (Westphal, 1969). They were soon interpreted as relatively cloud-free regions. They are therefore dark in the visible, since the bright regions on Jupiter are the most cloudy. Radiative transfer calculations have shown that the atmosphere of Jupiter can be sounded as deep as 6–8 bar at 5 μm wavelength in hot spots, which is the deepest level sounded in the optical range. The dynamical formation of hot spots is still poorly understood: they seem connected to strong convective cells, the hot spots being a region of downward convection, with strong vertical descent winds. The upper atmosphere is similarly aspired downwards, and the cloud particles are vaporized in the process, owing to the higher pressure–temperature encountered in the descent, leaving a very clear atmosphere. The downward flux of the atmosphere also explains the strong desiccation in condensed molecules, such as H_2O, NH_3 and H_2S, which has been measured by the Galileo probe. The upward-convective regions of the atmosphere should, on the contrary, present high cloud opacity and a saturated abundance in condensable molecules, as the opposite processes would work. It has been suggested that the equatorial plumes, seen as large bright clouds in the equatorial region, could be identified with these upward cells: there is apparently a one-to-one association of plumes with the hot spots in pairs, as a visual inspection of the morphology of the North Equatorial Belt suggests. An interesting fact is that the plumes observed along the equator are regularly spaced, numbering 9–13, like the hot spots. The generation of the regular structure of plumes–hot spots could be due to a travelling wave in the atmosphere, called a Rossby wave (Ortiz 1999).

Composition

The composition of Jupiter in heavy elements gives important clues for the understanding of its formation. The Galileo probe measurements have shown an enrichment by a factor of 2–3, compared with the solar composition, in the following elements: C, S, Kr, Xe and

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

Ar. The same is true for N, although the condensation of NH_3 introduces more difficulties in the measurements, and therefore larger uncertainties, with a deep abundance found at about 3.6 times the solar composition in nitrogen. This is also supposed to be the case for oxygen, present in H_2O on Jupiter, although the meteorological conditions in the hot spots where the probe descended were very desiccated and prevented any firm conclusion about the deep abundance of oxygen. Such enhancements are attributed to the scenario of formation of Jupiter from the solar nebula. First, the accretion of PLANETESIMALS (these small condensed objects, probably similar to comets or asteroids, are the elementary bricks of the solar system) forms a planetary core. When a core mass of about 10 Earth masses is reached, the proto-Jupiter begins to accrete the gas in the solar nebula, composed mainly of H_2 and He. Since the core does not contain the most volatile gases, degassed from the planetesimals, this mechanism can explain an enrichment in heavy elements, compared with hydrogen and helium.

The case of helium is particular, because of interior processes, at depths where hydrogen is condensed in metallic form: the lack of miscibility of He in metallic H_2 induces a phase separation of He droplets falling into the interior. As a result, He is depleted in the outer layers of the atmosphere, as is observed by Galileo, and the release of gravitational energy, contributes to the internal source. The depletion of neon is explained similarly by interior processes, by dissolution of neon in helium droplets. Depending on the temperature of the formation of planetesimals, several other elements could also be depleted, such as nitrogen (most of the nitrogen should be present in N_2, a very volatile gas). In Jupiter, a similar enhancement in nitrogen to that for the other elements is found: this implies a very low temperature for the formation of the planetesimals, of the order of 30 K only, much lower than the temperature at Jupiter's orbit, which is of the order of 160 K, and lower also than the temperature in the region of formation of the Oort cloud comets, in the Uranus–Neptune region, of the order of 55 K. Two explanations are competing: either the planetesimals forming the core of Jupiter came from the outer limits of the solar nebula, with much lower temperatures than in the Jovian vicinity, or Jupiter itself was formed at a larger distance from the Sun than its present orbit, and migrated to its present position as a result of viscous damping in the early solar nebula. The latter hypothesis is now considered seriously, after the discovery of extrasolar giant planets very close to their central star, a system which is considered to be impossible to form in a solar system formation scheme without migration of the protoplanet.

Temperature and atmospheric structure

Before the direct measurements by the Galileo probe, the temperature structure of Jupiter was measured with accuracy down to the 1 bar level only, from remote sensing ground- or space-based observations (stellar or radio occultation, infrared spectroscopy). The general features of the temperature structure were therefore already well known before Galileo, but only for the upper atmosphere: at pressures greater than 0.6 bar, the temperature increases towards the interior. The temperature lapse rate is limited by the convective instability, which transports the internal heat to the external layers. In the upper atmosphere, on the contrary, solar photons are absorbed by the atmospheric gases (H_2, CH_4) and hazes. This upper atmosphere heating generates an increase of temperature in the upper atmosphere. The heating from above (by solar radiation) and from below (by convection) induces the formation of a temperature minimum, at a level called the tropopause, which is situated on Jupiter at about 0.6 bar with a temperature of 110 K. The horizontal variations of temperature at the tropopause are usually low, of a few degrees kelvins for a given pressure level between equator and pole, except in some local areas such as the the GRS where larger temperature gradients have been found. The atmospheric structure of Jupiter has been measured accurately by the Galileo probe, at the location of the probe entry site, in a hot spot environment. Figure 3 shows the measured temperature profile. As anticipated by previous models (but never measured before), the tropospheric profile measured by Galileo is found to follow closely an adiabatic gradient, which corresponds to the maximum temperature gradient supported by an atmosphere in a convective regime.

The temperature profile in the upper atmosphere shows very distinctive and interesting features, with first strong heating above an isothermal region in the stratosphere, and oscillations in the upper part of the profile, which are attributed to gravity waves (figure 3). Gravity waves are the analogs in a gaseous atmosphere of the waves seen at the surface of a lake. The importance of

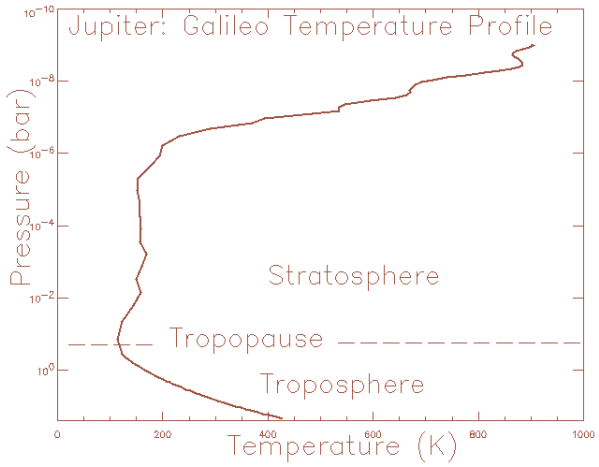

Figure 3. Temperature profile of Jupiter (after Seiff *et al* 1998 *J. Geophys. Res.* **103** 22857).

these waves in PLANETARY ATMOSPHERES is due to the transport of heat and momentum they can dissipate in the upper stratosphere. They could provide the missing link between the transport of internal heat in the upper troposphere to the external, radiative layers. The propagation of gravity waves directly depends on the atmospheric thermal profile: they propagate only in the upper atmosphere, when the temperature gradient is lower than the adiabatic gradient, which corresponds to the region above about 0.6 bar. The strong heating seen in the thermal profile could be partly due to the dissipation of the large-amplitude gravity waves, seen in figure 3 as the oscillations in the upper part of the curve.

Clouds

Even though the origin of the colors of the clouds of Jupiter remains unknown, the Galileo measurements have given new insight into the atmospheric structure and the vertical disposition of the clouds (see also CLOUDS IN PLANETARY ATMOSPHERES). The cloud structure revealed by the Galileo probe was very specific to the particular location of the probe entry site, within a hot spot area, and it is still difficult to reconcile the models for more typical regions on Jupiter, with the measurements in a very localized and particular region. The direct measurements by the probe revealed three cloud layers, vertically separated: a first cloud around 0.5 bar, corresponding to the expected position of the ammonia cloud, a second cloud layer with a base at 1.34 bar, which could be the expected ammonium hydrosulfide cloud, and a detached cloud deeper at 1.6 bar which could be a thin water cloud consistent with the low water abundance found by the probe. To the surprise of the investigators, no deeper cloud layer was found, down to 22 bar, where the transmission from the probe stopped. There was no trace of the expected water cloud at 5 bar or below. For a solar composition (and *a fortiori* for a larger than solar abundance of oxygen), a ubiquitous H_2O cloud is expected to form on Jupiter. The observations by the orbiter have now been interpreted, and they extend the probe measurements to other places on Jupiter, with the difficulties inherent to remote sensing observations where vertical structures are not easily disentangled. Some observations by the orbiter have now convincingly proved the presence of water clouds in several places. A deep and ubiquitous water cloud is out of range of the optical observations, but in several places the water clouds are apparently transported upward by strong convection, up to observable levels. Such clouds, similar to the tropical convective clouds on Earth, are also associated with lightning and with water vapor abundance in the atmosphere larger than in the hot spots. Observations by the Galileo Orbiter continue to study the cloud structure of Jupiter, progressing towards a global understanding of cloud variations between zones and belts of Jupiter. The difference in cloud structure between belts and zones is interpreted as mostly due to a difference in opacity of the cloud layers. The composition of the cloud particles is not easily measured by remote sensing observations, and the Galileo probe had no instrument with the ability to measure the composition of cloud particles. The cloud composition is therefore mostly inferred from thermodynamics arguments and from the knowledge of the composition of the gaseous atmosphere. The bright and white clouds observed in the Jovian belts are thought to be mostly composed of ammonia particles. It is nevertheless quite plausible to have a mixture of cloud particles in a given cloud layer, owing to the vigorous convection at work in many parts of the Jovian atmosphere. Water, ammonia and ammonium hydrosulfide could all be part of the upper cloud particles. The coloration of the belts can be caused by a small amount of chromophores, sulfur or phosphorus compounds being possible candidates for their composition. The clouds of Jupiter therefore still keep many of their mysteries.

Aurorae

On Earth, a polar AURORA is observed when charged particles from the solar wind precipitate into the atmosphere, exciting the atmospheric molecules which then emit light by de-excitation processes. The charged particles are guided along the magnetic field lines. The geometry of the magnetic field therefore also governs the location of the precipitation, mainly in the polar regions. On Jupiter, similar processes have been observed regularly since the first detection of polar emissions in H and H_2 by the INTERNATIONAL ULTRAVIOLET EXPLORER satellite in 1979, followed by the Voyager observations in 1979 and 1980. The differences from the Earth's aurorae are mainly due to the difference in atmospheric composition, with hydrogen dominating Jupiter's atmosphere, instead of oxygen and nitrogen in the Earth's atmosphere. The main atmospheric effects expected from the precipitation of charged particles are threefold:

1. direct excitation of molecules, followed by de-excitation by emission of photons,
2. thermal heating of the atmosphere, followed by enhanced thermal emission, and
3. chemistry induced by charged particles in the atmosphere subject to the auroral precipitation.

The UV emission observed since 1979 is due to electronic transitions of H_2 and H, and is relevant to the first mechanism. The primary particles coming from the magnetosphere (high-energy electrons or ions, see JUPITER: MAGNETOSPHERE) decelerate into the atmosphere and produce a large number of secondary electrons, which again excite the atmospheric molecules. These processes take place in the upper atmosphere, mainly between the nanobar and millibar pressure levels.

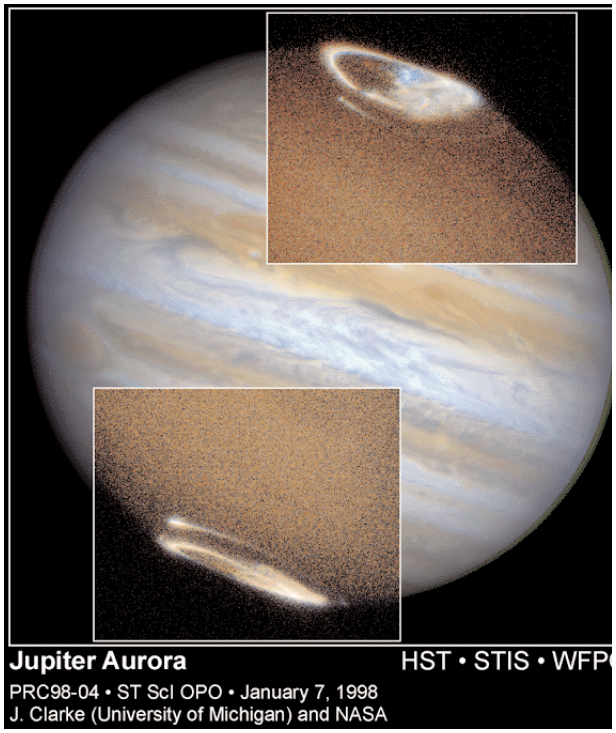

Figure 4. Auroral emissions of Jupiter, observed from Hubble Space Telescope. A visible image of Jupiter is superimposed with ultraviolet polar regions images taken with the STIS UV imager of HST.

Thermal emission of the atmosphere has also been observed in methane infrared emissions. Methane acts as the main radiator in the upper atmosphere of Jupiter. The energy deposited by charged particles is therefore mainly radiated by methane, in particular from its strong band at 7.8 μm. In the near infrared, emissions of a particular ion, H_3^+, have also been observed by ground-based spectroscopy. This molecular ion is a very peculiar molecular assembly, with three protons linked by two electrons, and, because of its high reactivity, it is an important constituent of the ionosphere of hydrogen atmospheres. Its strong infrared emissions have been detected in the mid-infrared (2–4 μm).

All these emissions have also been observed with imaging instruments, giving access to maps of the emissions and allowing us to correlate them with the geometry of the magnetic field (figure 4). Galileo observations have also observed emission in the visible wavelengths, on the night side of Jupiter, which are probably due to H_2 emissions between electronically excited bands of H_2. These observations give the most detailed maps of the aurorae to date. The geometry of the magnetic field is beautifully visualized in these images, with a north magnetic pole shifted compared with the geographic pole and an auroral oval descending toward 60° latitudes for longitudes close to 180° and tangential to the north pole on the other side.

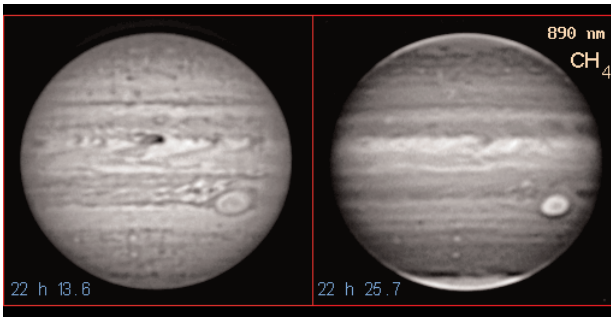

Figure 5. Jupiter observed at Pic du Midi (9 July 1996): left, image in broad red filter, showing the usual contrasts in the cloud structure; right, image in methane filter at 890 nm, enhancing the contrasts over the highest altitude clouds. The polar haze, the equatorial belt and the GRS are particularly prominent.

Auroral precipitations may also have a role in the chemistry of the atmosphere of Jupiter. The polar regions of Jupiter are covered by a high-altitude haze, which is permanently present, and limited to the regions above 60° north and south. These hazes are best visualized in images taken in filters with strong atmospheric absorption (such as methane or hydrogen band filters), which are more sensitive to the upper atmospheric contrasts (figure 5). The composition of this haze is still unknown, but a possibility is that it could be formed by heavy hydrocarbons formed from the chemistry of methane induced by charged particles. The formation of heavy hydrocarbons in a hydrogen-dominated atmosphere is a very peculiar process, unique in the solar system, and it is therefore highly interesting for planetary modeling.

New observations of Jupiter, its satellites and environs have been made by Cassini, Galileo, the Hubble Space Telescope, the Chandra X-ray Observatory and Earth-based radio and optical telescopes during the CASSINI spacecraft's flyby. The Galileo spacecraft has been in orbit around Jupiter since December 1995 while Cassini observed Jupiter from 1 October, 2000 to 31 March, 2001. Cassini made its closest approach on 30 December, 2000, at a distance of about 9.7 million kilometers (6 million miles). Data from the flyby observations show that Io leaves a magnetic footprint on Jupiter's upper atmosphere which appears as a spot of ultraviolet emission that remains fixed underneath Io as Jupiter rotates. The specific physical mechanisms responsible for generating these emissions are not well understood, but in general the spot seems to arise because of an electromagnetic interaction between Jupiter's magnetic field and the plasma surrounding Io, driving currents of around 1 million amperes down through Jupiter's ionosphere. The other Galilean satellites may also leave footprints, and the presence or absence of such footprints should illuminate the underlying physical mechanism by

revealing the strengths of the currents linking the satellites to Jupiter.

Jupiter's x-ray aurora has been thought to be excited by energetic sulfur and oxygen ions precipitating from the inner magnetosphere into the planet's polar regions. High spatial resolution observations demonstrate that most of Jupiter's northern auroral x-rays come from a hot spot located significantly poleward of the latitudes connected to the inner magnetosphere. The hot spot seems to be fixed in magnetic latitude and longitude and occurs in a region where anomalous infrared and ultraviolet emissions have also been observed. From the data it is inferred that the particles that excite the aurora originate in the outer magnetosphere. The hot spot x-rays pulsate with an approximately 45 min period, a period similar to that reported for high-latitude radio and energetic electron bursts observed by near-Jupiter spacecraft. These results invalidate the idea that Jovian auroral x-ray emissions are mainly excited by steady precipitation of energetic heavy ions from the inner magnetosphere. Instead, the x-rays seem to result from currently unexplained processes in the outer magnetosphere that produce highly localized and highly variable emissions over an extremely wide range of wavelengths.

From Jupiter to brown dwarfs

The recent detection of brown dwarfs has placed Jupiter in a new perspective: Jupiter is not only the largest planet of the solar system, it is also now an intermediate step between planets and stars. Low-mass stars, known as brown dwarfs, have been detected with masses as low as 10 Jupiter masses. An interesting question in the formation of stars and planets is the question of the differences in composition which are expected as a result of different formation processes. Brown dwarfs are supposed to form from a central condensation in a nebula, but Jupiter, as all the planets, was formed within the solar nebula by accretion processes, starting from solid planetesimals. Since the planetesimal composition is depleted in the most volatile elements, they induce a planetary composition different from the nebula. Indeed, the composition of Jupiter is found to be enhanced in heavy elements. In stellar terminology, Jupiter is described as having a high metallicity, compared with the solar composition. On the other hand, a brown dwarf forming from its own nebula would be expected to have a composition mostly similar to its nebula. Nevertheless, it must be emphasized that many stars are formed in multiple systems, and the theory of formation of binary systems is not fully understood yet. The distinction between star and planetary formation may therefore be more complex than this simple description. When more measurements become available on brown dwarfs, and, it is hoped, on extrasolar giant planets, the measurement of metallicity will be a major point to discriminate between possible scenarios of formation. This is probably one of the most challenging problems for an understanding of the formation of giant planets.

Jupiter: Magnetosphere

Jupiter's magnetosphere is the cavity surrounding the planet which contains and is controlled by Jupiter's magnetic field (figure 1). It reaches to a distance of ~60 Jupiter radii on the dayside of the planet (one Jupiter radius, R_J, is taken to be 71 373 km), and extends into a long comet-like tail on the nightside which has a diameter of ~300–400 R_J and a length of at least 3000 R_J. Jupiter's field is confined to this cavity by SOLAR WIND PLASMA WAVES which flow away from the Sun throughout the solar system, and bound the magnetosphere on the outside. Because the solar wind is supermagnetosonic in the planet's rest frame, a bow shock stands in the flow upstream from the cavity, at a distance of ~75 R_J on the dayside, across which the solar wind is slowed, compressed, and heated. The location of the boundary of the magnetosphere, the magnetopause, is determined by the condition of pressure balance between the shocked solar wind plasma (termed the magnetosheath) on one side, and the magnetospheric plasma and field on the other. On the inside of the cavity, the magnetospheric magnetic field lines extend down into the ionosphere and upper atmosphere (thermosphere) of the planet (see JUPITER: ATMOSPHERE), such that the magnetosphere, ionosphere, and thermosphere are strongly coupled together. The plasma inside the magnetosphere contains contributions from both Jupiter's ionosphere and the solar wind, consisting mainly of ionized hydrogen and helium, but by far the most important plasma source is the Galilean moon IO, which orbits deep inside the magnetosphere at a radial distance of 5.9 R_J, and liberates about 1 ton s^{-1} of sulfur dioxide gas (comparable to the production rate of an active comet). Consequently, the magnetospheric plasma is dominated by the presence of ions of sulfur and oxygen. The most important source of momentum and energy for the magnetosphere is the planet's rotation at a period of 9 h 55 min, such that the most important dynamics result from the presence of the Io plasma source deep within the rapidly rotating magnetosphere. However, as in the case of the EARTH'S MAGNETOSPHERE, solar wind coupling at the magnetopause may contribute significantly to the dynamics of the outer regions, and certainly to the formation and properties of the nightside magnetic tail.

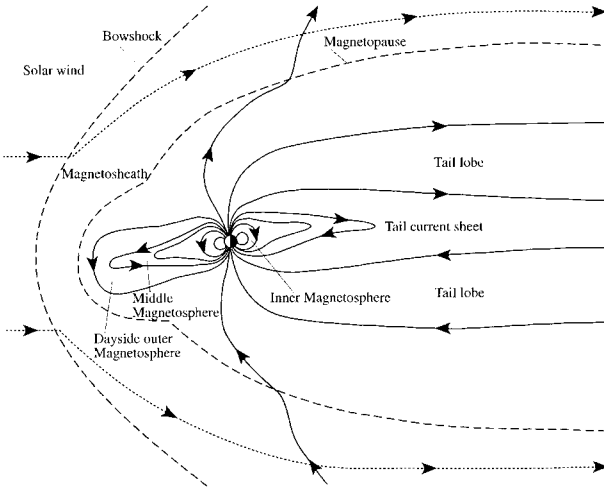

Figure 1. Sketch of Jupiter's magnetosphere in the noon–midnight meridian plane, with the Sun to the left and the solar wind blowing from left to right. The arrowed solid lines are the magnetic field lines, while the dashed lines are the magnetopause and bow shock, as indicated. The dotted lines are plasma streamlines.

Discovery and exploration

The discovery that Jupiter generates an intense magnetic field via dynamo currents flowing in its interior, was made in the 1950s from the observation that the planet is a source of radio emissions in the decametric (~10 MHz) and decimetric (~1 GHz) wave bands (see MAGNETOSPHERES: JUPITER, RADIO EMISSIONS). The decimetric emission is SYNCHROTRON RADIATION generated by gyrating energetic (~10 MeV) radiation belt electrons trapped by Jupiter's magnetic field near the equatorial plane within a few R_J of the planet. The spatial structure of this emission and its variations with planetary rotation indicated that the magnetic field is dipolar in form, like the Earth's, with the magnetic dipole axis tilted by ~10° relative to the planetary rotation axis. The POLARIZATION of the radiation, however, showed that the polarity of the field is opposite to Earth's, with field lines running from the northern hemisphere of the planet, via the equatorial regions, to the southern hemisphere. Whilst this decimetric emission is very steady in time, apart from a modulation at the planetary rotation period, the decametric radiation is instead characteristically bursty, and varies in intensity over several orders of magnitude on time scales of the order of minutes, with an averaged power around a hundred times that of the decimetric emission. Although the first to be discovered, by Burke and Franklin in 1955, the details of the decametric mechanism remain to be understood in detail. However, it is thought to involve emissions at the cyclotron frequency from ~keV electrons accelerated in the magnetosphere, which move along the magnetic field lines towards Jupiter's ionosphere. The upper cut-off frequency of 40 MHz then corresponds to the cyclotron frequency of the highest field strength accessible to these particles over the Jovian poles, equivalent to 1.4–10^{-3} T. This remarkably large field is about twenty times the strength of the Earth's polar field, despite the fact that Jupiter's radius is more than ten times that of the Earth. In 1964, Bigg also discovered that part of the decametric emission is directly influenced by the position of Io, thus providing the first evidence of a complicated electrodynamic interaction

between Io and the jovian magnetosphere–ionosphere system. In 1974, Brown using ground-based optical observations also discovered the existence of a large cloud of neutral sodium atoms surrounding Io, which was followed in subsequent years by optical observations of gas and plasma tori in the vicinity of Io's orbit, composed of the atoms and ions of sulfur and oxygen.

In situ exploration of Jupiter's environment began in November–December 1973 with the fly-by of the NASA PIONEER 10 spacecraft, followed by Pioneer 11 in 1974, VOYAGER 1 and 2 in 1979, the European Space Agency's ULYSSES in 1992 (en route to the Sun's polar regions; see SOLAR WIND: ULYSSES), culminating in the insertion into orbit of the NASA GALILEO MISSION spacecraft in 1995. At the time of writing only the results of the initial analyses of Galileo data are available, mainly concerning the interactions of the Galilean moons with the magnetospheric environment (see MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS). Most of the information described here, therefore, has been derived from the five earlier fly-by missions, augmented by radio and optical observations from Earth. The Pioneer spacecraft were instrumented principally to measure the jovian magnetic field and energetic particle environment at energies above ~1 MeV. The Voyager spacecraft made the first detailed *in situ* measurements of thermal plasmas at lower energies, at 10–100s eV and 10–100s keV, and of plasma waves. Similar measurements were also made by Ulysses. The trajectories of these spacecraft are shown projected onto Jupiter's orbital plane in figure 2, together with the locations of nominal magnetopause and bow shock positions. The *X* axis points towards the Sun, and the *Y* axis from dawn to dusk across the magnetosphere. It can be seen that all these spacecraft explored the pre-noon dayside magnetosphere on their inbound passes, and that Pioneers 10 and Voyagers 1 and 2 passed through the pre-dawn nightside sector outbound. All these trajectory segments were confined to the near-equatorial region. In contrast, Pioneer 11 passed out of the magnetosphere near noon at northern latitudes of ~33°, while Ulysses exited near to dusk at southerly latitudes of ~37°. Since the APOAPSIS of the Galileo spacecraft has also been confined mainly to the local time sector between midnight and dawn during the main phase of its mission, it can been seen that, while the dawn side of the magnetosphere has received considerable observational study, the dusk side remains almost unexplored.

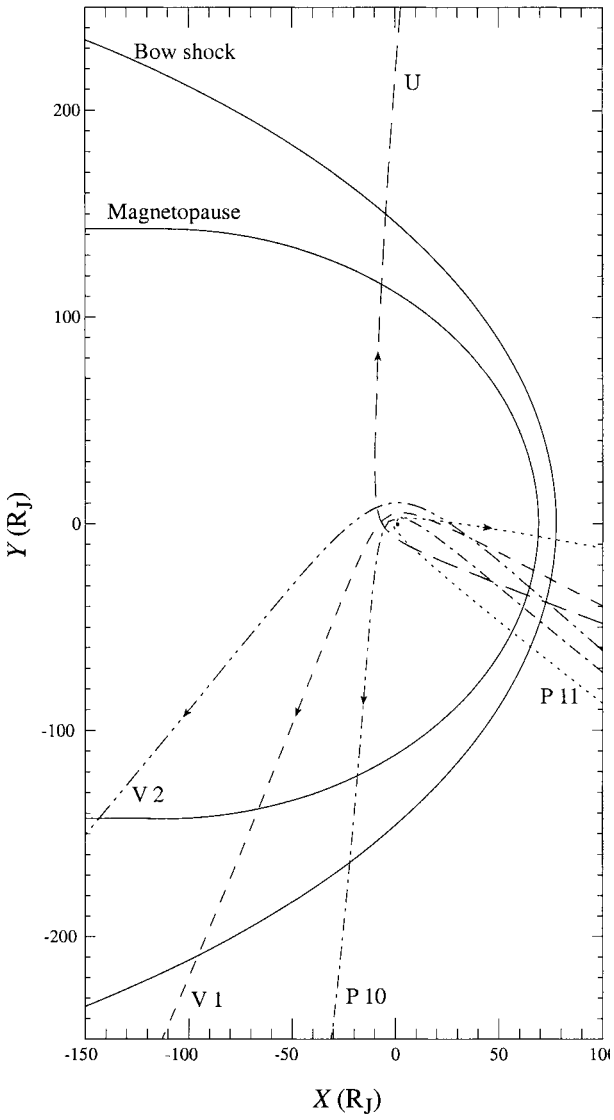

Figure 2. Trajectories of the five fly-by spacecraft relative to Jupiter, projected onto Jupiter's orbital plane. *X* points towards the Sun and *Y* from dawn to dusk. P 10 and P 11 refer to Pioneers 10 and 11, V 1 and V 2 to Voyagers 1 and 2, and U to Ulysses. Arrows are plotted in the direction of spacecraft motion on the outbound portions of the trajectories. Also plotted are the average positions of the bow shock and magnetopause (adapted from D E Huddleston *et al* 1998 *J. Geophys. Res.* **103** 20075–82).

Jupiter's magnetic field

Internal planetary field

Although the main features of the magnetic field produced by Jupiter's internal currents were inferred from radio observations prior to the first measurements by spacecraft, *in situ* data are required for detailed characterization. A recent model based on fits to the fly-by data, constrained also by Earth-based observations of jovian auroral emissions associated with the magnetic footprint of Io, indicates a best-fit centered dipole axis which is inclined at 9.5° to Jupiter's spin axis towards system III longitude 201°. The corresponding dipole moment is $4.26–10^{-4}$ T R_J^{-3}, such that the surface field is $0.4–10^{-3}$ T at the magnetic equator and approximately double that at the poles (neglecting the dynamical flattening of Jupiter's figure which increases the dipole polar surface field to ~$1.0–10^{-3}$ T). However, large quadrupole and octupole moments are also present which produce

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

significant asymmetries in the near-planet field, in particular increasing the peak surface field in the northern polar regions to ~1.5–10^{-3}, in agreement with the value obtained from the 40 MHz upper cut-off in the decametric emission.

Size of the magnetosphere

Using the above value of the dipole moment, a simple estimate can be made of the expected size of the magnetospheric cavity in the solar wind, based on pressure balance across the magnetopause. If magnetospheric plasma pressure is neglected such that the internal pressure is wholly magnetic, and taking a nominal solar wind dynamic pressure of ~0.1 nPa at Jupiter's orbit, a simple calculation shows that in the subsolar region (i.e. in the equatorial region near noon) the boundary should lie at a distance of ~35 R_J. In contrast, the fly-by observations of the dayside magnetopause, suitably adjusted to take account of the outward flaring of the boundary away from noon (see figure 2), indicate a typical distance of ~60 R_J. Furthermore, the response to variations in solar wind dynamic pressure indicates a much 'squashier' system than expected, with subsolar boundary positions varying between ~40 and ~80 R_J, indicating a position which varies inversely as the ¼ or (1/5) power of the dynamic pressure, compared with the (1/6) power expected for a dipole magnetic field. The reason for the great inflation of the magnetosphere, and for its 'squashy' nature, lies in the fact that (unlike Earth), the magnetospheric plasma makes a substantial contribution to the internal pressure, at least comparable to that made by the field.

Inner magnetosphere

The structure of the magnetic field within the cavity as revealed by spacecraft observations is indicated schematically in figure 1, which shows a sketch of the field lines in the noon–midnight meridian plane. Four basic regions are identified, whose boundaries are defined by the magnetic field lines. The inner magnetosphere is defined by the torus-shaped region of field lines which cross the equatorial plane within ~5 R_J of Jupiter's center. The field in this region is essentially an undisturbed planetary field, which contains the radiation zone of synchrotron-emitting energetic electrons. This region is distinguished from the middle magnetosphere, which bounds it on the outside, by the lack of significant electrical currents flowing in the plasma, such that the outer boundary of the region essentially coincides with the inner boundary of the Io plasma torus where strong equatorial currents begin. However, the inner region is affected by the fringing field of the latter currents, which produce a nearly uniform northward field in the inner region of strength ~200 nT. This field is directed opposite to the southward planetary field in the equatorial plane, but is much weaker than the latter, since even at ~5 R_J the equatorial dipole field is still 3400 nT.

Middle magnetosphere

As indicated above, the middle magnetosphere is characterized by the presence of strong azimuthal (eastward) electric currents flowing in the plasma near the equatorial plane whose magnetic effect distends the field lines outwards from the planet, as shown in figure 1. In the equatorial plane this region extends from the inner edge of the Io plasma torus at ~5 R_J to an outer limit on the dayside which depends upon the degree of extension of the magnetosphere, and lies typically ~15 R_J inside the magnetopause. For a typical ~60 R_J magnetopause position at noon, therefore, the outer edge of the middle

Dirac House, Temple Back, Bristol, BS21 6BE, UK

magnetosphere current sheet lies at ~45 R_J. On the nightside, the current sheet merges continuously into the current system of the magnetospheric tail. Figure 3(*a*) shows a sketch of the equatorial currents of the middle magnetosphere which, to a first approximation, close azimuthally around the planet, and the adjacent equatorial tail currents which flow from dusk to dawn across the system. The tail currents close north and south over the tail lobe magnetopause to form two D-shaped solenoidal current systems back-to-back, as shown in the cross section in figure 3(*b*). The full thickness of the current sheet is ~5 R_J, and the current within it, and hence the perturbation field produced, falls with distance from the planet approximately as $r^{-1.5}$. The value of the exponent depends somewhat on distance and local time, but is in any case considerably smaller than the r^{-3} dependence of the planetary dipole field. Consequently, while in the vicinity of Io's orbit the perturbation fields of the current sheet are relatively small compared with the planetary field (as indicated above), such that the field lines remain basically dipolar in form, they become dominant at distances beyond ~15 R_J. In the latter region the low latitude field is thus characterized by strong radial fields which point outwards from the planet north of the current sheet, and inwards to the planet south of the sheet, as shown in figure 1. At the center of the current sheet the field is weak and points south. The total current flowing in the annular middle magnetosphere current sheet (excluding the tail system) is ~200 MA.

Within ~30 R_J of the planet the current sheet is centered close to the planetary dipole equatorial plane, tilted at 9.5Â° to Jupiter's spin axis as indicated above. With increasing distance, however, the current sheet increasingly departs from this plane due to two effects. The first is that, as the dipole axis rotates around with the planet, the information about the rotation is communicated to the outer regions at a finite speed. Consequently, at a given distance from the planet the effective position of the dipole is increasingly retarded in azimuth relative to its true position. Within ~30 RJ the delays are insignificant, but beyond this distance the effective information propagation speed is ~40 RJ h–1 (~750 km s–1), leading to observable delays. The second effect is the 'hinging' of the current sheet in the magnetic tail, where the plane of the sheet departs from the dipole equator and becomes aligned with the tail axis (defined by the flow of the solar wind), as shown in figure 1. This effect becomes apparent at down-tail distances beyond ~35 R_J.

Outer magnetosphere

The outer magnetosphere is a dayside region observed during the inbound passes of the fly-by spacecraft of uncertain local time extent, in which there is no evidence of an equatorial current sheet. Instead, the field in this region, although rather variable, points on average to the south in the equatorial region, in the direction of the planetary equatorial field, and overlies the middle magnetosphere closer to the planet. The region is thus bounded by the magnetopause on one side, and by the middle magnetosphere on the other. A TRANSITION REGION of disordered field may occur between the outer and middle magnetosphere regions (particularly well marked on the inbound Ulysses pass), where the equatorial field undergoes sharp changes indicative of the presence of plasma current layers, but which are not ordered by magnetic latitude or planetary rotation period. The thickness of the outer magnetosphere in the equatorial region is ~15 R_J, and the average equatorial field strength varies between ~5 and ~15 nT, depending on the degree of extension of the magnetosphere. In all cases, however, the field is significantly stronger than that of the planetary dipole, due to the fringing effect of the current sheet field.

Magnetic tail

The magnetic tail on the nightside of the planet consists of two tail lobes of oppositely directed flux where the field is relatively uniform and strong, pointing away from the planet in the northern lobe and towards the planet in the southern lobe, which are separated by the thin (few R_J) equatorial current sheet mentioned above, where the plasma carries the required electric current from dusk to dawn across the tail. Overall, the tail has an approximately cylindrical shape with a diameter of ~300–400 R_J, such that the two lobes are D-shaped in cross section, as shown in figure 3(*b*). The field strength in the lobes falls with increasing distance as the tail expands in radius, reaching ~2 nT at a down-tail distance of ~150 R_J as measured by Voyager 2 (see figure 2). By analogy with Earth, it seems probable that the tail is formed by MAGNETIC RECONNECTION at the dayside magnetopause between the interplanetary and magnetospheric field, which results in the formation of open magnetic flux tubes which map from the planet's polar cap, through the magnetopause, and into interplanetary space (figure 1). The flow of the solar wind then carries them onto the nightside of the planet, where they are stretched out to form the tail lobes. As they are stretched out down-tail, the open tubes slowly sink in towards the center plane of the tail, where they reconnect again within the current sheet, returning closed magnetic flux tubes, attached to Jupiter at both ends, back towards the planet. However, where the reconnection and return flow take places in the jovian tail is at present unknown. On the basis of this model we may estimate that the lobe field lines flow towards the current sheet at a speed of a few tens of km s^{-1}, such that they remain 'open' for several Earth days. Consequently, the length of the tail (equal to the speed of the solar wind times the length of time for which lobe field lines remain open) will be several thousand R_J (i.e. a few AU). The amount of magnetic flux in each lobe is ~4–10^{11} Wb, corresponding to a region of

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

~10° latitude surrounding each magnetic pole at ionospheric heights.

Bending of the field meridian planes

For a pure dipole, field lines lie in planes of constant longitude relative to the dipole axis. However, the planetary field lines at Jupiter are noticeably bent out of such meridian planes, associated with the existence of azimuthal fields directed either eastward (in the sense of planetary rotation) or westward around the magnetic axis. The bending of meridian planes is of interest because it provides information about the transfer of magnetic forces between one plasma region and another connected by the magnetic field. Two major effects are illustrated in figure 4(*a*), which shows a view looking down onto the jovian magnetosphere from above the northern pole, and shows field lines in two regimes of latitude mapping out from Jupiter's ionosphere to the equatorial plane. The field lines in the high-latitude region mapping into the outer magnetosphere are bent away from noon and towards the tail as a consequence of the solar wind interaction, such that in the northern hemisphere (as shown) the perturbation fields are eastwards on the dusk side of the magnetosphere and westward on the dawn side (and vice versa in the southern hemisphere). The current system responsible is that of the magnetopause and tail (as sketched in figure 3(*b*)).

At lower latitudes, however, the field lines mapping to the middle magnetosphere current sheet show a consistent sense of bending independent of local time (insofar as it has been measured), with azimuthal fields which are westward above the current sheet (as shown), and eastward beneath it. This pattern of field bending is associated with a torque on the magnetospheric plasma which acts to spin it up towards the angular velocity of planetary rotation, i.e. it is associated with the transfer of angular momentum from the thermosphere/ionosphere to the magnetosphere, as will be discussed further below. The current system responsible is sketched in figure 4(*b*), and involves a radially outward current in the equatorial plane which closes along magnetic field lines through equatorward currents flowing in the ionosphere. Typically, outside the current sheet the observed azimuthal field is a small fraction of the radial field, such that the radial currents are a correspondingly small fraction of the azimuthal current. Figure 4(*a*) shows that the two effects discussed here produce similar effects which are difficult to separate in the dawn magnetosphere where most observations have been made. However, the Ulysses observations at dusk demonstrate that the two effects are separately present, one dominant in the middle magnetosphere, the other in the outer magnetosphere.

Jupiter's plasma populations and their dynamics

Sources of plasma mass and momentum

The nature of the plasma dynamics in a planetary magnetosphere depends on the nature of the plasma sources and sinks, and the nature of the transport processes which convey the plasma from the former to the latter. The plasma sources include the solar wind at the outer boundary and the planet's ionosphere at the inner boundary, together with the surfaces and atmospheres of any moons that happen to orbit within the cavity. The sources of momentum include the antisunward flow of the solar wind on the outside, and the planet's rotation

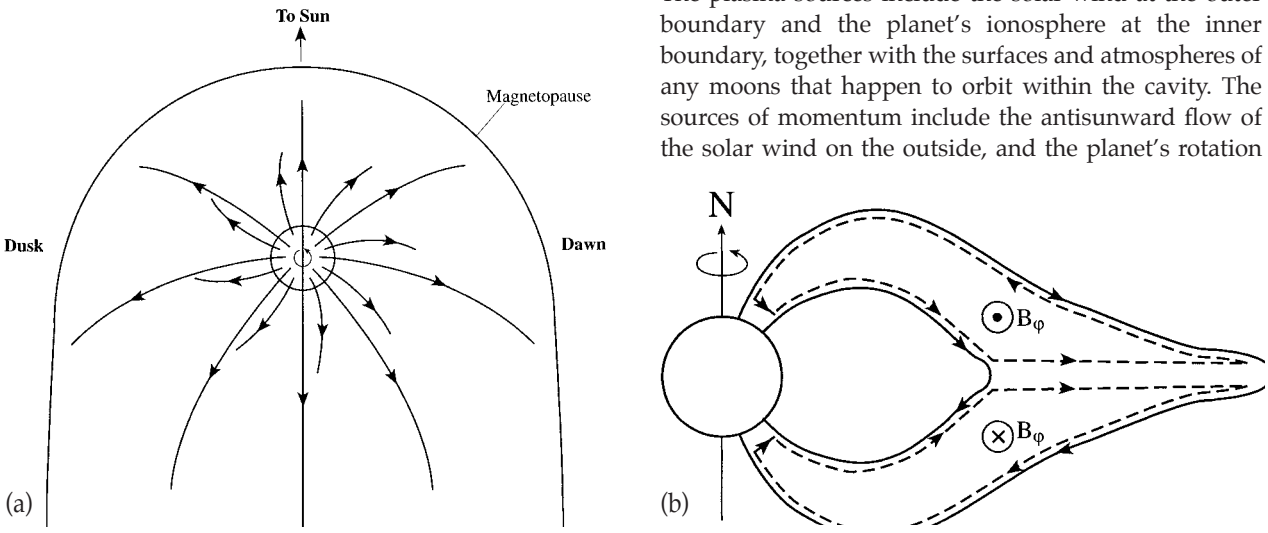

Figure 4. (*a*) Sketch of field lines emanating from the northern hemisphere of Jupiter projected onto the equatorial plane, showing the bending of the field lines out of meridian planes. High-latitude field lines mapping to the outer parts of the magnetosphere are bent away from noon by the interaction with the solar wind. The current system responsible is the magnetopause–tail system. Lower-latitude field lines mapping to the middle magnetosphere current sheet are bent consistently in the clockwise sense, associated with the transfer of anticlockwise planetary angular momentum from the thermosphere/ionosphere to the magnetosphere. (*b*) Sketch of the current system associated with planetary angular momentum transfer. The arrowed solid lines are magnetic field lines, and the dashed lines show the direction of current flow. The circled symbols marked B_φ indicate the direction of the azimuthal perturbation magnetic field produced by these currents, out of the diagram north of the current sheet, and into the diagram south of the sheet.

on the inside. Solar wind interaction at the boundary carries magnetospheric flux tubes from the dayside to the nightside in the outer regions of the magnetosphere, as discussed above in relation to the formation of the magnetic tail, from which closed flux tubes eventually return flowing sunward through the central regions of the magnetosphere. In the absence of such flows, the magnetospheric plasma and field will rotate with the planet, the angular momentum being transferred by ion–neutral collisions at the feet of the field lines in the lower ionosphere.

Brice and Ioannidis in 1970 were the first to consider the relative importance of these two flow systems at Jupiter. Flows of plasmas and embedded magnetic fields are associated with an electric field which is transverse to both the velocity vector $\boldsymbol{V}$ and to the magnetic field $\boldsymbol{B}$, given by $\boldsymbol{E} = -\boldsymbol{V}-\boldsymbol{B}$. The overall strength of a flow system can then be measured by the voltage associated with its electric field, since by Faraday's law 1 V is equivalent to the transfer of 1 Wb s^{-1} of magnetic flux embedded in the flow. The electric field associated with the solar wind driven flow is directed from dusk to dawn across Jupiter's magnetosphere, and by analogy with the Earth, the associated voltage can be estimated to be ~1 MV (i.e. the transfer through this flow system of ~1 MWb s^{-1} from the dayside to the tail in the outer regions, and the return of the same amount, in the steady state, in the central regions). The electric field associated with rotation is directed radially outwards in the equatorial plane, and for rigid corotation with the planet (i.e. rotation with the same angular frequency as the planet) the associated voltage is ~400 MV. Rotation with the planet is thus by far the most important flow at Jupiter, although as indicated above, this statement does not preclude the dominance of solar wind driven effects in the outer regions and magnetotail.

Estimates indicate that both the solar wind and the ionosphere represent sources of a few -10^{28} ion s^{-1} for Jupiter's magnetosphere, consisting principally of hydrogen (i.e. protons, together, of course, with sufficient electrons to keep the gas electrically neutral overall). The corresponding mass sources are a few tens of kg s^{-1}. The ionospheric source also uniquely provides molecular hydrogen ions, H^+_2 and H^+_3, as minor constituents, while the solar wind provides He^{2+} and traces of heavier ions such as carbon. The identification of all these species within the jovian plasma has confirmed the presence of both sources. The major discovery of the Voyager fly-bys, however, was that the jovian system is not dominated by a hydrogen plasma as had previously been anticipated, but by a sulfur and oxygen plasma which originates from the sulfur dioxide atmosphere of the volcanic moon Io, which orbits at a distance of 5.9 R_J. The source rate is estimated to be ~3–10^{28} ion s^{-1}, similar to the solar wind and ionospheric sources, but because the ions are heavy, with a mean mass of ~21 amu, the corresponding mass source of ~1000 kg s^{-1} is overwhelmingly dominant. The sodium source at Io, though easily visible in optical emission, is less than this by a factor of around a hundred, and is thus negligible in overall terms. Recent estimates indicate that the moon EUROPA, which orbits at a radial distance of 9.4 R_J, is also a significant source of oxygen plasma originating from the surface water ice, with rates of ~2–10^{27} ion s^{-1} and corresponding mass rates of ~50 kg s^{-1}. The plasma dynamics of Jupiter's magnetosphere is therefore dominated by the consequences of the presence of strong heavy-ion sources lying deep within a rapidly rotating magnetosphere.

The Io plasma torus

The Io plasma which exists within Jupiter's magnetosphere originates principally from electron-impact ionization of the clouds of sulfur and oxygen atoms which orbit in the vicinity of Io, originating in the latter's atmosphere (see IO: PLASMA TORUS). The density of these atoms peaks at a few tens of cm^{-3} near the orbit of Io, with oxygen being the more numerous species as expected from the sulfur dioxide source, and falls off by an order of magnitude within ~1 R_J on either side. These neutral particles orbit with Io at Keplerian speeds of ~17 km s^{-1}, being influenced only by the gravitational force of Jupiter. When these atoms are ionized, however, the resulting ions and electrons suddenly sense the electromagnetic environment as well, that is to say the southward ~2000 nT magnetic field of the planet, and the ~0.1 V m^{-1}

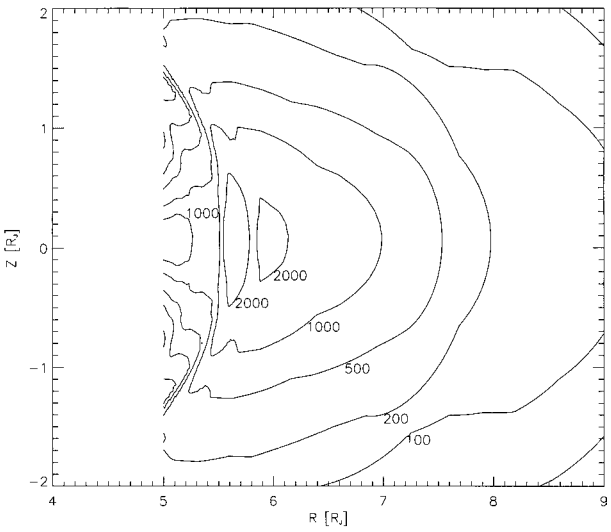

Figure 5. Contours of electron density in the Io plasma torus in the meridian plane, determined from Voyager 1 PLS data. The vertical scale is distance from the centrifugal equatorial plane, while the horizontal axis is distance from Jupiter's spin axis, both in R_J. The numbers on the contours give the electron density, equal to the ion charge density, in units of electrons cm^{-3}. (Taken from F Bagenal *et al* 1997 *Geophys. Res. Lett.* **24** 2119–22.) outward-directed electric field associated with the ~70 km s^{-1} flow of the near-corotating plasma. The effect of these fields is such as to cause the charged particles immediately to drift with the plasma at the corotation speed (they are 'picked up' by the plasma flow), and also to acquire a gyratory speed about the field lines equal to the difference between the corotation and Keplerian speeds, equal to ~55 km s^{-1}. This corresponds to a 'thermal' energy of ~250 eV for oxygen ions and ~500 eV for sulfur, but only 0.01 eV for electrons. Subsequently, the ions are cooled by Coulomb collisions with the electrons, and the consequently heated electrons are cooled by collisional excitation of the low-lying energy levels of the ions, thus leading to the observed optical emission from the torus.

The most detailed information about the low-energy plasma distribution which results from these processes was obtained during the inbound passage of Voyager 1. Figure 5 shows contours of electron density (equal to the ion charge density) which have been derived from these data. The principal population is the warm plasma torus which, in the equatorial plane, extends outwards from a jovicentric distance of ~5.6 R_J. The ions in this region consist of two populations, a suprathermal population of recently ionized few 100 eV particles (increasing in energy with increasing distance, up to ~2 keV at ~10 R_J), comprising ~10–20% of the population, and a cooled population with a temperature of ~60 eV (also increasing with distance up to ~300 eV at 10 R_J). The electron temperature in this region is ~10 eV. In the inner part of the warm torus, within ~7.5 R_J, there are approximately equal numbers of sulfur and oxygen ions, with the oxygen being principally O^+, while the sulfur is roughly equally divided between S^+ and S^{2+}. Outside this distance, the plasma is richer in oxygen, possibly due to the Europa source, with roughly equal numbers of O^+ and O^{2+}, and the density of S^{3+} becomes comparable with those of S^+ and S^{2+}. Inside ~5.6 R_J the plasma cools precipitately to form the cold plasma torus near the equatorial plane at distances of ~5.0–5.4 R_J. The ion and electron temperatures in this region are just a few eV, and the composition is a somewhat sulfur-rich combination of S^+ and O^+.

The distribution of the torus plasma along the field lines is determined by a balance between the plasma pressure force, the magnetic mirror force, the centrifugal force, the gravitational force due to Jupiter, and a field-parallel electric force which is required to ensure that the ion and electron charge densities are equal at all points. Apart from the latter, the most important physical effect is that the centrifugal force tends to compress the plasma at the centrifugal equator (the point of maximum distance along a field line from the planetary spin axis), while this compression is resisted by the plasma pressure. In the warm torus, equilibrium is reached for a scale height along the field lines away from the equator (the distance over which the density falls by a factor of ~2.7) of ~1 R_J. In the cold torus, however, the scale height is reduced by the lower temperatures to ~0.3 R_J.

The spatial structure of the torus plasma across the field lines reflects both the distribution of the atomic gas sources in the vicinity of the orbits of Io and Europa, together with the nature of the cross-field transport mechanism. Because the outwardly directed centrifugal force on the plasma is dominant (being much greater, certainly, than the inward force of Jupiter's gravity), flux tubes containing high-density plasma from the Io source will tend to 'fall' outwards to larger distances, restrained by the frictional drag of ion–neutral collisions at the feet of the field lines in the ionosphere. These flux tubes will be replaced by tubes containing lesser densities moving inwards, it being ultimately supposed, of course, that some mechanism (presently unknown) exists for emptying the flux tubes of their plasma content at large distances. This picture explains the basic cross-field structure shown in figure 5, which is indicative of rapid transport of warm dense plasma away from Jupiter at distances beyond the neutral gas sources. However, the inward transport from those sources towards Jupiter is much weaker, such that the plasma has time to cool by radiation, collapses onto the centrifugal equator due to the reduced pressure, and then recombines, thus explaining the existence and properties of the cold torus population.

Although the basic physical picture of outward radial transport of the torus plasma by centrifugally driven flux tube interchange thus seems clear, the details of the process are not yet determined, including basic time and spatial scales, and is simply parameterized in many theoretical models by an empirically determined spatial diffusion coefficient. Observationally, the warm torus plasma is found to pervade the equatorial current sheet out to the outer boundary of the middle magnetosphere at several tens of R_J. Due principally to the expansion of the flux tubes, the equatorial ion/electron charge density falls from at peak of ~3000 cm^{-3} (during the Voyager 1 flyby) near the inner edge of the torus at ~5.7 R_J, to ~70 cm^{-3} at ~10 R_J (as in figure 5), and down to ~0.1 cm^{-3} at several tens of R_J. The fraction of suprathermal particles in the population appears to increase with distance, however, such that the average energy also increases, rather than falling as expected for an expanding plasma. Typical values are a few 100 eV. Sporadic enhancements of low-temperature plasma are also observed in the dayside outer magnetosphere, correlated with decreases in the strength of the magnetic field. We may conjecture that these represent plasma fragments which have become detached from the middle magnetosphere current sheet.

Hot plasma population

The outwardly diffusing Io torus plasma is not, however, the only population which is present in Jupiter's

magnetosphere. Observations by the Voyager and Ulysses spacecraft have shown that a low-density but high-energy population is also present, consisting of roughly equal numbers of protons and heavy ions (mainly sulfur and oxygen). The number density and average energy of this population both increase on moving towards the planet, before falling near the inner edge of the warm torus. In terms of the above discussion, we may picture this low-density population to be transported radially inwards as the high-density torus plasma is transported radially outwards. Indeed, evidence has been found in Galileo data for sporadic localized inward injections of hot ions within the current sheet at distances between ~10 and ~30 R_J. These injections have aspects in common with SUBSTORMS at Earth, but at Jupiter they are not confined to the nightside but occur at all local times. Inward transport of this plasma results in compression and heating as observed, the energy required being derived ultimately from the outward 'falling' torus plasma. The presence of the hot plasma thus acts partially to suppress this transport.

The hot plasma density is much less than that of the warm torus plasma throughout the system, being ~10^{-2} to 10^{-3} cm^{-3} in the outer regions, increasing to perhaps ~1 cm^{-3} in the inner part of the Io torus. These particles thus make little contribution to the overall mass or charge density compared with the low-energy plasma, except perhaps in the dayside outer magnetosphere. However, their average energy is sufficiently large that they make the dominant contribution to the plasma pressure at all points except for the innermost part of the warm torus where the extreme warm plasma density (figure 5) and the falling hot ion temperature combine to produce comparable warm and hot plasma pressures. In the outer part of the magnetosphere the hot ion temperature is a few tens of keV, with the distribution having a non-Maxwellian high-energy tail extending above 1 MeV. The average energy then increases with decreasing distance, reaching a peak of ~2 MeV at ~7 R_J according to Voyager 1 measurements, before falling to ~100 keV inside Io's orbit at 5.9 R_J. Electrons are also present with comparable energies but significantly lower densities, such that they make a smaller contribution to the pressure. It is these energetic particles in the inner part of the warm torus which form the source of the radiation belts within the inner magnetosphere. From the vicinity of Io's orbit these particles are more slowly diffused inwards due to the presence of fluctuating electric fields driven by winds in the thermosphere, gaining further energy as they do so. This input is balanced in the steady state by particle flux and energy losses in the inner magnetosphere which are due to wave-induced particle precipitation into the atmosphere, absorption by ring material and moons, and (for electrons) synchrotron radiation.

A key feature of the hot ion population is that within the outer part of the middle magnetosphere its pressure is comparable with that of the magnetic field. As a consequence it 'inflates' the planetary field to form the current sheet structure observed in this region (figure 1), a process which also inflates the magnetosphere beyond the size expected for pressure balance between the solar wind and the planetary magnetic field alone, as discussed above. The distended field lines then provide the inward force (the $\boldsymbol{j}$–$\boldsymbol{B}$ Lorentz force of the azimuthal current) which in the steady state balances the outward pressure gradient of the hot plasma. The Io torus plasma also plays a role in current sheet formation, though a lesser one, since the field must also provide the inward force necessary to balance the centrifugal and pressure gradient forces of this population. With regard to the dominant hot plasma population, Voyager observations indicate that the equatorial pressure remains greater than that of the field throughout the outer part of the middle magnetosphere, while falling below that of the field inside ~10 R_J, due to the rapidly increasing strength of the dipole field. Consequently, as noted above, the perturbation fields produced by the plasma at and inside these distances becomes smaller than the planetary field, such that the field geometry then assumes a quasi-dipolar form.

Plasma flow and field bending

Observations of the plasma flow within the middle magnetosphere, extending outwards from the orbit of Io, generally confirm a primary plasma flow in the sense of planetary rotation as discussed above. However, departures from rigid corotation are observed which are due to two main effects. The first occurs in the main source region of the torus plasma in the vicinity of Io's orbit, where neutral atoms are ionized and 'picked-up' by the plasma. Because ANGULAR MOMENTUM is continuously provided to the newly ionized particles, the plasma in this region rotates more slowly than for rigid corotation, by an amount which is just such that the ion–neutral collisions in the lower ionosphere provide the required torque. Ground-based spectroscopic observations of the plasma, together with *in situ* data from Voyager 1, indicate that the plasma flow is slowed by ~4 km s^{-1} in a ~2 R_J-wide region centered near to Io's orbit by this effect (the rigid corotation speed is 74 km s^{-1}). Outside this region, near-rigid corotation is resumed.

As the torus plasma diffuses radially outwards, however, angular momentum must again be continuously added to maintain plasma rotation at near-rigid speeds. If no angular momentum is added, conservation of plasma angular momentum requires the azimuthal speed of the plasma to fall inversely as the distance from the spin axis, while for rigid corotation the speed must increase in direct proportion to this distance. In order to

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

maintain near-rigid corotation of an equatorial outwardly diffusing plasma, the angular momentum flux into the equatorial region must be constant, independent of distance. For radial mass fluxes corresponding to the Io source, it turns out that in the inner part of the torus, the required angular momentum flux can be supplied by ion–neutral collisions in the lower ionosphere for only minimal departures of the flow from rigid corotation. In this region, therefore, the plasma very nearly rigidly corotates with the planet outside the source region. However, with increasing distance from the planet a given area of the equatorial plane becomes connected via the magnetic field to a decreasing area of the ionosphere, which is located nearer to the rotation axis. Consequently, the ionospheric torque ultimately becomes small even for large departures from corotation. Thus beyond a certain radial distance, depending on the Io mass flux and the ion–neutral friction in the ionosphere, the azimuthal velocity is expected to break away from near-rigid corotation, to peak, and then to fall inversely with distance in the regime where the input of angular momentum becomes small. Voyager observations indicate that the flow is near to that expected for rigid corotation to equatorial distances of ~20 R_J, where the azimuthal flow speed is ~200 km s^{-1}, and falls below rigid corotation at larger equatorial distances. Voyager data for a relatively compressed magnetosphere indicate flows in the outer regions which do not fall with distance as then expected, but rather remain at values which are a factor of ~2 lower than rigid corotation speeds. When the magnetosphere is more extended during intervals of low solar wind dynamic pressure, however, the flow speeds in the outer regions are rather lower than this relative to rigid corotation, as indicated by data from both Pioneer 10 and Ulysses.

We should mention that, while in the above discussion we have described the input of angular momentum from the planet as being due to ion–neutral collisions in the lower ionosphere, this angular momentum is actually transmitted to the equatorial plasma via the bending of the field lines out of meridian planes which was shown in the inner part of figure 4(*a*), and whose current system is shown in figure 4(*b*). The $\boldsymbol{j}$–$\boldsymbol{B}$ force associated with the radially outward current in the equatorial plane (into the diagram) acts to increase the speed of a subcorotating equatorial plasma, while the $\boldsymbol{j}$–$\boldsymbol{B}$ force of the closure currents in the ionosphere acts in the opposite direction as a drag force on the rotation of the thermosphere. The corotation of the thermosphere is maintained to the extent allowed by viscous coupling to the corotating denser atmosphere beneath.

Flows in the outer magnetospheric regions are exceedingly uncertain at the present time. Outbound Voyager 2 measurements established the existence of a layer of plasma adjacent to the dawn tail magnetopause at ~150 R_J which was flowing antisunward, opposite to

the direction of planetary rotation. The flow speed was ~500 km s^{-1} in a layer a few tens of R_J wide. The nature of the overall dynamics, however, concerning, e.g., the ultimate loss process for Io plasma, and the interaction between planetary and solar wind driven flows in the tail, are yet to be determined.

Jovian auroral emissions

Auroral emissions from the polar regions of Jupiter were first detected in the UV by two independent spacecraft missions: the International Ultra–Violet Explorer (1979) and the Voyager spacecraft (1979 and 1980). These particular emissions result from direct excitation of atmospheric species by collisions with precipitating energetic magnetospheric electrons (see JUPITER: ATMOSPHERE). Auroral features were subsequently observed at various other wavelengths including the infrared (thermal emissions) and near–infrared (particularly from ionospheric H^{3+} ions). The IR aurora is excited by particle heating, or from Joule heating by large–scale current systems closing in the ionosphere. The auroral regions have also been associated with strong x–ray signatures, and furthermore are powerful sources of radio emissions.

Since these early measurements, data of much higher spatial and temporal resolution have become available both at visible wavelengths from the SSI instrument on the Galileo spacecraft, in the UV from the HUBBLE SPACE TELESCOPE (HST), in the infrared from Earth–based telescopes, as well as x–ray emissions from the CHANDRA x–ray observatory. These observations show that there are perhaps four main types of auroral emission. First is the Io footprint (IFT) emission, a ~1 MR emission which maps magnetically to the vicinity of the moon. There is also an auroral 'tail' stretching downstream of the IFT in the near–corotating flow. The Io related emissions are thus quite distinct from the other jovian auroral emissions, and are clearly visible in figure 6. It is understood that the corotational electric field which is developed by the relative motion between Io and the near–corotating magnetic field lines flowing past the satellite induces a potential difference of approximately 500 kV between the outer and inner faces of the moon. This potential is thoght to cause currents to flow from Io toward the ionosphere, both northward and southward, along the outer portion of the magnetic flux tube linking the satellite to the ionosphere. Return currents then flow along the inner portions of the flux tube towards Io. This circuit closed through the jovian ionosphere and also in the ionosphere of the moon, and is associated with the Io–controlled decametric radio emissions (see JUPITER: RADIO EMISSIONS). This 'unipolar inductor' model explains the spot of aurora associated with the upward directed portion of the current system (implying downward flowing electrons), i.e. the IFT, but does not explain the existence of the 'tail' of auroral brightness downstream of Io by as much as ~180°. However, recent work by Hill and Vasyliunas (2002) associates this downstream wake signature with the plasma currents which are required to accelerate the newly injected plasma from Io up to approximate corotation with Jupiter. Recent images indicate that footprint and wake auroras are also associated with Europa and Ganymede, and it seems likely that these features are due to the same downtail mass–loss process.

The second auroral component is the main auroral oval (MAO), which has been the subject of a plethora of reports recently. The MAO is the most significant emission in terms of energy output, and takes the form of circumpolar bands around both the northern and southern magnetic poles, consistently observed in all the wavebands mentioned above. Although this emission is of variable width (on average ~500–1000 km) and intensity (up to a few MR), it appears to be essentially continuous in local time, at dipole co–latitudes of ~16°, closer to the pole than the Io flux tube. It has been known for some time that this auroral region maps magnetically to the middle magnetosphere. Recently it has been suggested to be associated with the current system which maintains corotation of the equatorial plasma in the middle magnetosphere. Specifically the MAO is thought to be associated with the upward–directed field–aligned current at the inner edge of the magnetosphere–ionosphere coupling current circuit shown in figure 4(*a*). The former of the models cited above proposes an empirical model of the aurora, using estimates of the angular velocity of the plasma in the equatorial plane and a suitable magnetic field model. An interesting consequence of this model is that one would then expect the auroral brightness to anti–correlate with the dynamic pressure of the upstream solar wind. As the magnetosphere contracts, the angular velocity increases due to conservation of angular momentum, the currents go down and the aurora dims; conversely as the magnetosphere expands, the angular velocity decreases, the currents go up and the aurora brightens. It is thought that the hectometric radio emissions would also follow this modulation, although recent observations show that at least part of this radio emission exhibits impulsive increases which correlate positively with shocks in the solar wind.

The third component of the aurora is the high latitude diffuse emissions, which occur regularly and have a brightness of a few x 100 kR. These polar cap auroras are generally extended across the dusk side of the polar cap poleward of the MAO. At this time, a production mechanism for these emissions has not been suggested. More recent papers have also discussed a fourth feature which is seemingly a regular occurrence in the auroral regions. This feature appears consistently near magnetic local noon, and is reminiscent of the Earth's polar cusp. This is

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

referred to as a 'cusp–like' feature, which was reported by to be rapidly evolving, very bright (up to ~40 MR) and localised near noon. This feature lies poleward of the MAO and therefore it is conjectured that it may be controlled by pressure and/or magnetic field changes in the upstream solar wind. However, the intensity of this feature requires some form of acceleration mechanism, and could not be obtained simply by solar–wind particles flowing along open field lines (in the conventional 'cusp–like' sense).

The recent fly–by of Jupiter by the Cassini spacecraft en–route to Saturn (December, 2001), along with an intense HST campaign to complement Earth–based telescope observations, may help to unravel the response of the auroral regions to the upstream solar wind conditions monitored by Cassini.

Jupiter: Rings

The faint Jovian ring system was discovered in images taken by the spacecraft Voyager 1 in March 1979 and imaged in more detail by its sister craft Voyager 2 four months later. The density of these rings appears to be about a million times less than that of Saturn's rings (see SATURN: RINGS). This explains why, situated so close to the bright planet, they had never been observed from the Earth. Pioneer 11, which flew by the planet five years before the VOYAGER MISSIONS, had observed sudden variations in the number of charged particles orbiting around Jupiter at certain distances from the planet. Some scientists suggested that the absorption of particles by a ring was a possibility. Five years later this hypothesis was proved to be correct!

Within the diverse class of known PLANETARY RINGS, Jupiter's ring structure represents one of the extremes. Along with Saturn's E and G rings, it is among the most tenuous systems yet discovered. Such rings are of particular interest because the processes that dominate within them are very different to those in more substantial ring systems. Mutual collisions between particles are rare, and the particles making up these tenuous rings are expected to be dominated by electromagnetic effects and radiation drag forces. Small particles should also be short-lived in the high-radiation environment of Jupiter.

In this article, the properties of the Jovian ring system are reviewed; emphasis is placed on the findings of the GALILEO MISSION, since this work refines several interpretations of Jupiter's rings.

Morphology

The Jovian rings are the archetype of ethereal planetary rings: bands of very low optical depth containing micron-sized particles. This faint and diffuse ring system, as imaged by Voyager, consisted of three separate components: (1) a relatively bright narrow ring, referred as the main ring; (2) a vertically extended halo interior to the main ring; (3) a very tenuous ring, called the gossamer ring, exterior to the main ring.

Spectacular images from the Galileo spacecraft changed this picture somewhat. Galileo has been orbiting Jupiter and its moons since 1996. The spacecraft took three dozen images of the rings and small moons during orbits of Jupiter in 1996, and as a result of much improved observations by this mission, we now know that the rings have the following properties.

(1) The thin main ring is about 7000 km wide, extends between 1.71 and 1.81 Jovian radii ($1\,R_J = 71\,399$ km). The normal optical depth τ is about 10^{-6}. This ring has patchy (20–30%) brightness, with a maximum at $1.79R_J$ and a minimum around 127 850 km in the vicinity of Metis (figure 1).

(2) The thick toroidal halo ($\tau = 10^{-6}$) extends inwards from the main rings at $1.71R_J$ down to $1.4R_J$. Roughly 50% of the halo's brightness originates from a region within 700 km of the equatorial plane, while the halo is visible up to 10 000 km above and below the plane (figure 1).

(3) The gossamer ring, previously seen only in one Voyager image, is in fact two faint rings (with $\tau = 10^{-7}$) that are bounded by the orbits of the small ring-moons, Amalthea and Thebe (figure 2). The first, Amalthea's gossamer ring, is visible between the main ring's periphery and about $2.55R_J$, i.e. inwards of Thebe's orbit. Very faint material continues past Thebe's orbit to $3.5R_J$. The gossamer rings have thicknesses that are comparable to the maximum elevations of their bounding satellites above Jupiter's equatorial plane. When viewed edge-on, the top and bottom edges of the gossamer rings are about two or three times brighter than the body of the rings.

The composition of the ring particles could not be deduced from the Voyager images alone, ground-based observations are still very difficult, and the Galileo images are being analysed. However, to first order, we are concerned only to know whether the particles are made of ice or of rock (metal particles are unlikely on cosmochemical grounds). Because of the very short lifetime of micron-sized ice grains, it seems probable that the grains are rock rather than ice. Moreover, the small satellites closest to the ring are known to be rocky by virtue of their low albedo (see JUPITER: SATELLITES). This is also suggestive of a rock ring rather than an ice ring. Relative spectral reflectivity measurements show the ring material to be reddish, indicating that the rings could consist of small silicate grains.

Nature and origin

Particle lifetimes

The particles making up the visible Jovian ring are quite tiny since the distribution of particle sizes shows a peak around 2 μm. Such micron-sized grains reside in the fierce magnetospheric environment (see JUPITER: MAGNETOSPHERE). Accordingly, sputtering by energetic ions and electrons can be effective in destroying ring particles because the ejection process is efficient and because large fluxes of energetic particles are found in Jupiter's magnetosphere. Impacts by micrometeroids and other dust can also abruptly cause the demise of the rings. Elimination trough sublimation is not competitive on the non-icy materials at the distance of Jupiter from the Sun, but could be if instead the particles were water ice. The different lifetimes of a micron-sized grain in a Jovian ring against loss are summarized in table 1.

While ring grains are eroded and destroyed, their orbits are expected to evolve secularly under the influence of drag forces (plasma drag dominates). Table 1 shows that evolution times are similar to lifetimes for erosion and destruction.

Although none of these estimates is well determined because some pertinent parameters are not known accurately, the basic finding for Jupiter's rings is inescapable: particle lifetimes are short ($\leq 10^{2-3}$ years). The rings must be continually regenerated, by collisions with parent bodies, which may be the known small ring-moons or other unseen ones.

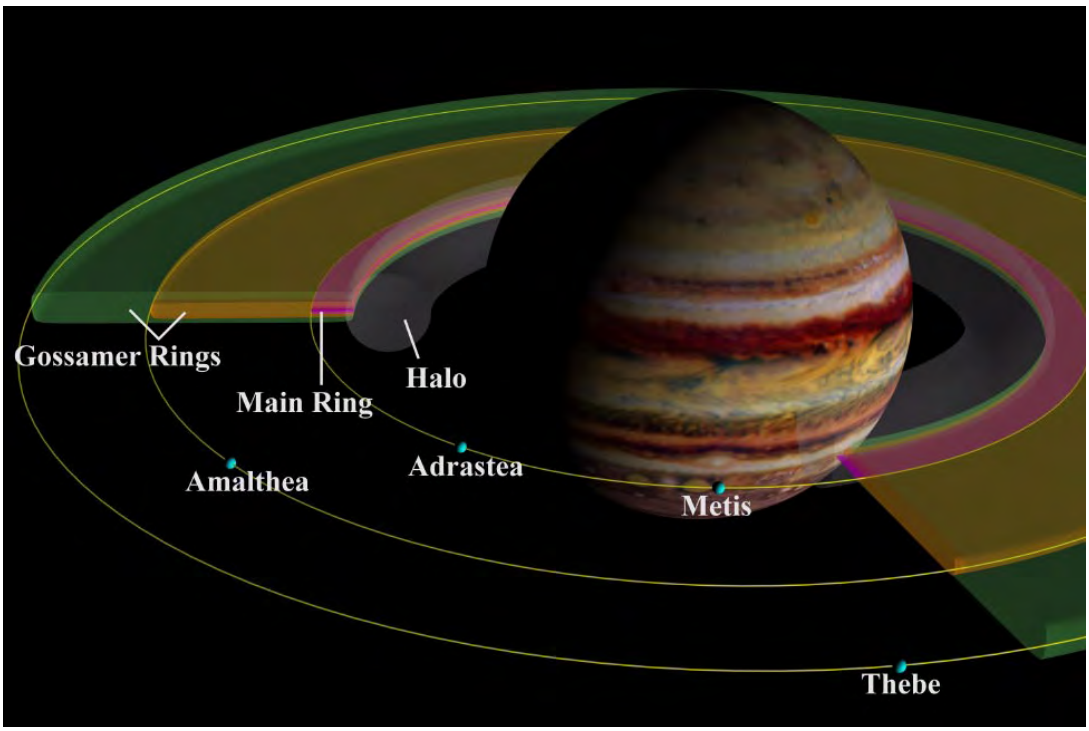

Figure 2. The entire Jovian ring system and small inner satellite orbits. This schematic drawing depicts the major components of Jupiter's rings and the four small satellites, Metis, Adrastea, Amalthea and Thebe. The relationship of the satellites' orbits to the rings can be seen. (Courtesy of Jonathan Joseph, Cornell University.)

The role of the known embedded satellites

A rich family of satellites surrounds Jupiter. In particular, there are four small inner satellites close to Jupiter: moving radially outward from Jupiter, we see Metis (mean radius $R = 20$ km), Adrastea ($R = 10$ km), Amalthea ($R = 90$ km) and Thebe ($R = 50$ km). Discovered in 1892 by Edward Barnard, Amalthea was considered to be the closest satellite to Jupiter for 87 years, until three other satellites, of which two are now the closest, were discovered by the Voyager probes in 1979.

Before the Galileo probe, it was still unclear what role, if any, was played by the satellites in the structure

Process	Lifetime (years)
Loss	
Magnetospheric erosion	$10^{3\pm1}$
Meteoroid erosion	$10^{5\pm1}$
Evaporation	10^{7}
Evolution	
Radiation forces	10^{2}–10^{5}

of the Jovian rings. But the unique morphology of the gossamer rings, as imaged by Galileo, can be generated only if the ring particles are collisional ejecta evolving radially inward from the satellites Amalthea and Thebe. The source of Jupiter's ring system and how it works is described below and in figure 3.

The environment of the small satellites closest to Jupiter is very hostile. Accordingly, their surfaces are exposed to hordes of energetic particles moving within the magnetosphere of the planet and to the bombardment by gas and dust particles originating in the volcanoes of Io, as well as by interplanetary meteoroids, or fragments of comets and asteroids, at speeds greatly magnified by Jupiter's huge gravitational field. However, satellites can be either sources or sinks for rings, depending how much ejecta is created in an impact and what fraction of that ejecta has sufficient speed to escape.

If the moon is too big, dust particles will not have enough velocity to escape the moon's gravitational field. With diameters of a few tens of kilometers, the small Jovian moons are perfectly suited for the ejection of debris created by the meteoritic bombardment. Moreover, typical escape speeds from the satellites are many tens of m s^{-1} for Amalthea and Thebe, and between 0–10 m s^{-1} for Adrastea and Metis. These escape speeds are lower than the orbital speeds, so ejected particles enter orbits that are much like those of their source satellites, both in their distance from Jupiter and in their slight tilt relative to Jupiter's equatorial plane. Due to Jupiter's oblateness, the tilted orbits wobble back and forth in only a few months. After a few years, the orbits have smeared into a cylindrical band. Observed from near the equatorial plane, the band looks rectangular rather than the familiar elliptical arc seen on Saturn's rings and Jupiter's main ring. As the grains drift inward, the rectangle will brighten toward the planet, and will contain an embedded bright bow-tie shape because the drifting particles retain their initial orbital inclinations.

Since ring-moons of 10 km radius are the most efficient source of collisional ejecta, the most obvious sources of the thin main ring are meteoritic impacts onto the satellites Adrastea and Metis. Note that each ring's vertical thickness would be affected by the inclination of the orbits of the inner satellites, which are struck by meteoroids. Thebe's inclination is the largest, Amalthea has a significant inclination, and Adrastea and Metis have no inclination. Thus, the thickness of each ring increases as you travel away from Jupiter. This also explains why the main ring is a *thin* ring.

Formation of the halo

The halo is probably composed of material that is evolving inward from the main ring. Over the time of an orbital revolution, the size of the typical particles shrinks since lifetimes are similar to evolution times, as shown in table 1. This explains why the visible halo grains are simultaneously closer to the planet and smaller than those of the main ring. Since the smaller grains are more susceptible to the electromagnetic forces, the halo

particles are some main ring particles that have been driven vertically by these electromagnetic forces. When halo orbits become highly distored, particles are lost in Jupiter.

Conclusion

In short, the Galileo probe's findings showed the intimate relationship between the Jovian rings and the satellites orbiting within them. These rings should be regarded as one example of the broad class of faint planetary rings. The G and E rings of Saturn certainly fall into this category, and the F ring shares some key characteristics. The dominant physical processes for diffuse rings are often different from those that apply to the denser rings of Saturn and Uranus (see also URANUS: RINGS). In particular, small particles last for limited times and so the rings must be continually regenerated if these rings are to be long-term members of the solar system. For the first time, scientists have identified the source and the nature of the Jovian ring material: dust blasted off the four small moons. The faint rings of the other giant planets (see e.g. NEPTUNE: RINGS) of the solar system are probably associated with many small moons, and it is expected that future spacecraft will reveal similar systems at Saturn and the other giant planets.

Jupiter: Satellites

As befitting the king of the planets, JUPITER is orbited by an entourage of at least 39 natural satellites in addition to its faint rings, intense radiation belts and occasional temporary visitors from Earth and the outer solar system. Named after Zeus' lovers and other mythological companions, Jupiter's moons can be divided into four groups on the basis of their sizes and orbits (table 1). Nearest the planet, four tiny inner moons lie embedded within Jupiter's tenuous rings and are the likely sources of the dust-sized particles that make up the ring system. Farther out are the Galilean satellites, four large worlds comparable in size with the Earth's Moon which vary systematically with distance from Jupiter in composition, appearance and geological activity. Two groups of captured satellites occupy the outskirts of the Jupiter system. The first four of these outer moons orbit in the direction of Jupiter's rotation, with orbits that are inclined at angles of 25°–29° to the planet's equator. The outermost four have highly inclined retrograde orbits, opposite to Jupiter's spin direction. In 2002, a team of astronomers discovered 11 new satellites by examining images taken in December 2001 and using later follow-up observations. It is estimated the new-found natural satellites are each about two to four kilometers (one to two miles) in diameter, and were probably passing rocks captured by Jupiter's gravity long ago. The satellites were formally announced by the International Astronomical Union on Circular No. 7900 (16 May 2002).

The Galilean satellites are large enough to be easily seen with inexpensive binoculars, devices that are far superior to the primitive instruments with which the moons were discovered in 1610. GALILEO GALOLEI is credited with first finding the four moons that bear his name and cited the existence of another gravitational center of movement in the universe as evidence to support the heretical hypothesis that the Earth and other planets revolved around the Sun. The Galilean satellites were also probably discovered independently by the German astronomer SIMON MARIUS, who named the moons on the basis of a suggestion by Johannes Kepler. Decades later, OLE RØMER of Denmark realized that the irregularities in the times of the eclipses of the Galilean satellites (used by mariners to determine longitude) were due to the changing distance between Jupiter and the Earth, and used this to make the first determination of the speed of light. Apart from Amalthea, first seen by E Barnard (the discoverer of BARNARD'S STAR, the second closest system to the Sun), the remaining satellites eluded detection until the 20th century. Because of their small sizes and proximity to Jupiter, the inner satellites Metis, Adrastea and Thebe went unseen until the VOYAGER explorations in 1979. Arriving four months apart on their way to the outer solar system, the two Voyager spacecraft also discovered Jupiter's rings and gave us our first detailed views of Amalthea and the surfaces of the Galilean satellites, including glimpses of the violent volcanic activity on Io.

Since December 1995, Jupiter has been orbited by an artificial satellite sent from Earth to study the planet and its rings, moons and magnetosphere. The GALILEO MISSION was launched in 1989 from the space shuttle Atlantis and took 6 yr to arrive at Jupiter following flybys of Venus, the Earth and two main-belt asteroids, Gaspra and Ida, the first such small bodies to be imaged by a spacecraft.

The mission was made up of two components: a Jupiter probe, which entered the atmosphere of the giant planet and relayed the first direct measurements of its composition, structure and dynamics, and an orbiter equipped with four remote sensing instruments sensitive to wavelengths from the ultraviolet to the thermal infrared along with a battery of instruments for monitoring the charged particles, waves and fields of Jupiter's space environment. Galileo has produced a number of new insights about Jupiter's satellites and rings, solving some of the mysteries arising from the Voyager data and presenting new puzzles. New observations of Jupiter's satellites have also been made during the Cassini spacecraft's flyby by Cassini, Galileo, the Hubble Space Telescope, the Chandra X-ray Observatory and Earth-based radio and optical telescopes. Cassini observed Jupiter from 1 October 2000 to 31 March 2001. Observational results include data on interactions of the Galilean moons with Jupiter's magnetic field. In the following sections we will summarize what has been learned so far from the space missions.

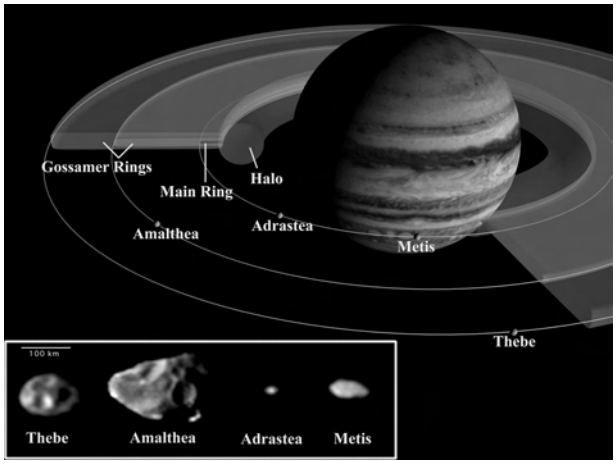

Figure 1. The inner satellites of Jupiter. (Courtesy of Cornell University and NASA.)

Inner satellites

With the exception of Amalthea, little was known about the small inner satellites of Jupiter prior to Galileo's arrival other than their orbits. The innermost pair, Metis and Adrastea, both orbit at the edge of Jupiter's brightest main ring at distances of 1.79 and 1.81 Jupiter radii (R_J) respectively from the center of the planet. Both lie within the Roche limit and would be disrupted by tidal forces if they had no internal strength. Their orbital periods are shorter (~7 h) than the period of Jupiter's rotation (~10 h); hence their orbits will gradually decay and they will ultimately fall into Jupiter. Unlike the other satellites, Metis and Adrastea orbit faster than Jupiter's plasma sheet, the dense swarm of trapped charged particles that corotates with the Jovian magnetic field. In contrast, Amalthea at $2.54R_J$ and Thebe at $3.11R_J$ have periods of about 12 and 16 h, respectively, and so they are overtaken by the faster corotating charged particles. All of the inner satellites are thought to be in synchronous rotation, having spin periods the same as their orbital periods so that they keep the same face pointed towards Jupiter at all times. Their densities and bulk compositions are unknown.

Distant imaging by Galileo allowed the shapes and sizes of the four inner satellites to be determined for the first time (see table 1 and figure 1) and also measured their colors and albedos. All are dark, red objects that become progressively redder with proximity to Jupiter. The coloration is similar to but darker than Io's, and could be due to contamination by sulfur compounds drifting inwards from Io. The orbital leading hemispheres of the inner satellites are 25–35% brighter than the trailing hemispheres, and their leading sides are also less red than their trailing sides. It was first thought that Amalthea's color dichotomy could be caused by charged particle implantation but, when the same hemispheric asymmetry was also found on Metis and Adrastea (where such implantation effects should be reversed), it was decided that the leading–trailing differences were due to impactors preferentially swept up on the moons' leading sides as they move in their orbits around Jupiter. The irregular shapes of the inner satellites suggest histories of bombardment and catastrophic disruption, and no geological features other than impact craters can be seen on their surfaces.

Jupiter's complex ring system is intimately related to the inner satellites (figure 1). Unlike the bright rings of Saturn, Jupiter's dark rings are probably made up of non-ice materials (see JUPITER: RINGS). The main, most prominent, ring extends from Metis and Adrastea inwards to $1.72R_J$ and is less than 30 km thick. Adrastea is located right at the edge of the main ring, while Metis orbits just within it. Reaching inwards from the main ring is the 'halo', a broad, diffuse cloud of charged dust particles levitated out of the equatorial plane by electromagnetic forces. Exterior to the main ring are two faint 'gossamer' rings trailing inwards from Amalthea and Thebe. The thickness of Thebe's gossamer ring is the same as the height of Thebe's orbital excursions above and below Jupiter's equatorial plane. A similar correspondence exists between Amalthea's orbit and the thickness of its gossamer ring. This confirms that the moons are the sources of the ring particles, probably debris kicked up by impacts. The ring particles are launched with orbital inclinations similar to their parent moons' and likewise oscillate above and below the equatorial plane. Because the particles spend less time on the equatorial plane than above or below, the gossamer rings have peculiar banded profiles, such that their margins appear brighter than the ring centers when viewed edge on. Metis and Adrastea appear to be the sources of the main ring. Interestingly, tiny Adrastea may contribute a greater share of ring particles than its larger companion. Adrastea is near the optimum size for shedding debris

from craters into space: smaller satellites present too little surface area for impactors to target, while larger satellites recapture more of their impact ejecta because of their greater gravity. The expected dynamical lifetime for ring particles is exceedingly short compared with the age of the Jupiter system, so the impact events that produced the currently observed particle population must have occurred relatively recently.

Galilean satellites

The Jupiter system is often likened to a miniature solar system because of the compositional gradation exhibited by its four largest moons (figure 2). Io (see below), the nearest to Jupiter of the four at $5.9R_J$, has a bulk density of 3.57 g cm^{-3}, corresponding to silicate rock and metal composition. EUROPA, at $9.4R_J$, has a bulk density of 2.97 g cm^{-3}, suggestive of dominantly silicate composition despite its icy exterior. GANYMEDE and CALLISTO have densities indicative of ice–rock mixtures with at least 40% ice by mass. At $15R_J$, Ganymede's density is 1.94 g cm^{-3} while Callisto, the farthest satellite ($26R_J$), has a density of only 1.86 g cm^{-3}. This compositional gradation is thought to be primordial, caused by the condensation of refractory materials in the warm, interior portions of the proto-Jovian nebula and of more volatile ices in the cooler outer reaches, in much the same way as the formation of planets in the solar system as a whole. Some of the compositional differences, particularly those seen on the surfaces of the satellites, may be due to geological activity as well. Ganymede, Europa and especially Io are heated by tidal flexing which powers their geological activity, along with modest contributions from the decay of radioisotopes and electromagnetic induction. The tidal flexing is driven by the eccentricities of their orbits, which are forced by the 1:2:4 Laplace resonance of their orbital periods: each time Ganymede completes one orbit of Jupiter, Europa orbits exactly twice, while Io undergoes four revolutions. Without this resonance to sustain it, the orbit of any of the satellites would soon circularize. The orbits of all three moons are gradually migrating outwards and will soon (i.e. in a few hundred million years) encounter a resonance with Callisto, possibly inducing activity on this geological late bloomer. Most of the energy dissipation in the satellite system takes place on Io, which as a consequence is the most active object in the solar system.

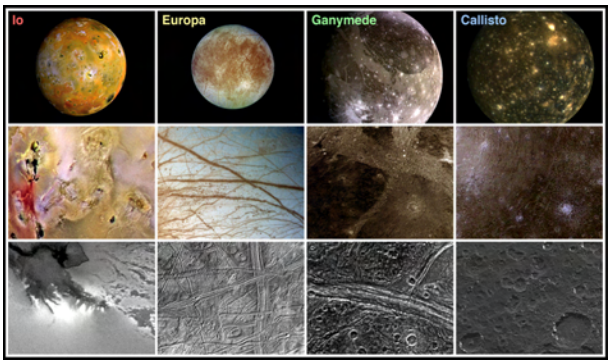

Figure 2. The four Galilean satellites. (Courtesy of DLR and NASA.) This figure is reproduced as Color Plate 27.

Io

Unique among solid objects in the solar system, Io's surface is devoid of recognizable impact craters. The amount of geological resurfacing necessary to obscure craters at their estimated present rate of formation is enormous—more than 1 cm of burial per year over the entire satellite. An even larger rate of resurfacing is required to account for the present heat flow observed from the moon (more than 2 W m^{-2}): assuming that this heat is carried by molten silicates at their liquidus temperatures, new materials must erupt at a rate of about 10 cm yr^{-1}, globally averaged. Comparisons between Io's appearance during the Voyager flybys and in Galileo pictures taken 20 yr later suggest that most of this resurfacing, over short time scales, is restricted to several dozen volcanic centers distributed more or less randomly around the globe. If so, the heat flow requires that fresh volcanic deposits tens of meters thick were emplaced in these active areas over the past two decades.

Volcanoes on Io have diverse morphologies often markedly different from their counterparts on Earth and Mars (see VOLCANISM AND GEOPHYSICS). They range from vast lava lakes such as Loki, the source of much of Io's thermal emission, to powerful plumes such as Pele that reach hundreds of kilometers in height and produce deposits large enough to be seen by the Hubble Space Telescope. Sulfur compounds such as SO_2 drive the plumes and paint Io's surface a surprising array of muted red, yellow and white hues. The lavas themselves are dark and generally lack the cones characteristic of terrestrial volcanoes. Galileo measured the thermal emission of the lavas with two different instruments during times when the moon was in Jupiter's shadow and found temperatures exceeding 1700 K, far hotter than the melting point of sulfur or even common silicate rocks such as basalt. Either the lavas are superheated prior to eruption or they are made up of materials with very high melting points. Magnesium-rich ultramafic magmas of the sort that commonly erupted on the early Earth are likely candidates. Some evidence consistent with this interpretation was found in the form of spectral absorption features at a wavelength of about 0.9 μm, which may indicate magnesium-rich silicate minerals such as orthopyroxene. The most persistent hot spots on Io seem to be located near the equator, consistent with models of tidal heating in the upper asthenosphere. Clusters of hot spots are found near the equator on both the Jupiter-facing (subjove) side and the side opposite Jupiter (antijove).

Io is a major polluter of the Jupiter system and the source of dust streams and plasma particles that diffuse throughout the Jovian environment. Sulfurous deposits from Io discolor Europa as well as the inner satellites. An

Dirac House, Temple Back, Bristol, BS21 6BE, UK

escaping cloud of neutral sodium atoms surrounds Io as it orbits Jupiter (along with even larger quantities of sulfur and oxygen, which are harder to see). Many of these atoms are subsequently ionized and swept up by the rotating Jovian magnetic field as it streams past Io. These electrons and ions make up a plasma torus that encircles Jupiter and wobbles up and down along with the Jovian magnetic field (which is inclined with respect to Jupiter's rotation axis). Energetic ions from the torus reimpact Io and eject even more particles, making the plasma torus self-sustaining (see IO: PLASMA TORUS). The motion of Jupiter's magnetic field past the conducting satellite also induces an electric potential across Io of some 400 000 V. Powered by this electrical generator, currents from Io modulate Jupiter's radio emissions and produce bright visible and ultraviolet glows in the polar regions of the distant planet, known as the flux-tube footprints. The footprints are electrically connected to Io along magnetic field lines running from Jupiter's high latitudes to the subjove and antijove points on Io's equator. Galileo imaged bright blue optical emissions from plume gases at these locations on Io while the satellite was eclipsed by Jupiter. These visible aurorae are probably produced by the flow of electrons through SO_2 vented by volcanoes. Other eclipse emissions at red and green wavelengths are not localized at the plumes and are likely to be due to oxygen and sodium in Io's tenuous atmosphere. In sunlight, a jet of neutral sodium can be seen escaping from Io in the direction away from Jupiter, apparently accelerated by the electric field and then neutralized by recombination.

Europa

Smallest of the Galilean moons, Europa was only distantly imaged by the Voyager spacecraft and remained the least explored of the four until the Galileo mission. Nevertheless, the satellite generated a great deal of interest because of the speculation that its icy exterior may harbor a subsurface sea of liquid water. Like Io, Europa is heated by friction as its shape is tidally deformed during each orbit of Jupiter—not enough to replicate Io's violent activity but perhaps enough to melt some of the ice and generate silicate volcanism on the sea floor. The Voyager investigators realized that its smooth, bright surface and paucity of recognizable impact craters indicated that the satellite was geologically young and ascribed its global system of lineaments (fractures, ridges and bands) to a thin ice shell overlying a ductile interior. On closer inspection by Galileo, Europa was revealed to have a variety of perplexing surface features that are unique in the solar system.

Two major terrain types dominate Europa's surface. Ridged plains are ubiquitous on the satellite and are made up of dense networks of crisscrossing lineaments with varying ages and orientations, testifying to a long history of tectonic activity. Concentrated near the equator but found sporadically at higher latitudes are the so-called chaos regions, thermally disrupted areas where the ridged plains have been erased by localized heating from below. The precise mechanisms by which these terrains formed are still hotly debated, and years of analysis and modeling will probably be needed before a consensus emerges. The most common landforms of the ridged plains are pairs of peculiar double ridges that often reach several hundred kilometers in length. They are typically 100–200 m high and less than 1 km across and are divided by a steep central valley. These ridge pairs appear to be part of a progression of tectonic features that begins with simple cracks in the ice surface. Icy material is deposited on the flanks of favorably oriented fractures by some cyclic process of extrusion and withdrawal, leaving ridge pairs with central valleys. As ridge pairs mature, their outer margins are darkened by as yet unidentified red-brown non-ice contaminants that discolor the surrounding surfaces to distances of several kilometers from the brighter medial ridges, forming striped 'triple bands'. Some ridges evolve into large, multiple-ridge sets composed of several individual ridge pairs, probably by repeated reactivation of crustal weaknesses associated with the ridges. Other lineaments have little observable relief and instead appear to be dilational bands caused by crustal spreading. Older surface features that are broken by these dilational bands can frequently be matched up through cutting and pasting the digital images, by removing the dilational bands and joining together the pre-existing crust like pieces of a puzzle. Intermediate landforms with characteristics of both ridges and bands are also observed. Many of the ridges and bands (but not fractures) are also strike-slip faults, commonly displaying left-lateral displacement in the northern hemisphere and right-lateral displacement in the southern hemisphere. A particularly puzzling class of lineaments are the cycloids or 'flexi', features resembling cracks, ridges and bands but having curved paths that abruptly change direction at ~100 km intervals, yielding arcuate patterns with semicircular sections joined by angular cusps.

Strong support for the notion of a subsurface ocean came from Galileo's first closeup pictures of chaos regions. One such site on Europa's trailing hemisphere, called Conamara, is an irregular depression about 100 km wide characterized by the thorough destruction of much of the original surface structure and replacement by an irregular jumble of lowlying ice with a red-brown stain similar to that of the triple-band margins. The remaining plate-like blocks of surviving crust have shifted, rotated and tilted from their original positions. Studies of other thermally disrupted areas suggest that such crustal blocks may gradually disaggregate in place. Two theories have been developed to explain these features. The first suggests that the chaos regions are the sites of crustal thinning and melting, leaving the crustal blocks adrift on near-surface liquid water analogous to ice floes in the polar regions of Earth. The second suggests that portions of the cold, dense surface subsided into warmer, low-density ice upwelling from below via

solid-state convection. Interestingly, many of the remaining crustal blocks in the Conamara chaos have large ridge sets and other heavy structures superimposed. Such heavy blocks should be among the first to founder if the surface were underlain by low-density ice; hence this observation is more consistent with the former explanation of the blocks as 'icebergs' floating on a higher-density liquid substrate.

The few impact craters scattered across Europa also suggest a thin ice crust. The largest (up to 50 km diameter) are flat, low structures surrounded by concentric fractures, tensional graben that may have formed as the ductile subsurface flowed to fill the newly created hole. The most recent large impact was Pwyll, a 26 km diameter crater on Europa's trailing side that still possesses a prominent set of bright rays. Because of the bombardment of the surface by charged particles from the plasma sheet, these crater rays are expected to be removed by sputtering erosion over time scales as short as a few million years. The continuous ejecta from Pwyll forms a dark-brown, 40 km diameter splotch similar in color to the chaos regions and the margins of the triple bands. The most fascinating aspect of Pwyll is its near total lack of relief: it is no deeper than 200 m below the level of the surrounding surface. For comparison, similarly sized impacts on Ganymede typically excavated enormous cavities 2 km deep. Either the Pwyll impact penetrated through the ice crust and the crater was flooded with liquid at the time it formed or the topography has subsequently slumped under its own weight by glacier-like flow. Europa's surface is extremely cold, however – less than 130 K on the equator at noon—and ice is as stiff as rock at such frigid temperatures. Even if the flatness of Pwyll is due to solid-state flow, the short time scale for topographic relaxation seems to require that the ice in the shallow subsurface is quite warm, perhaps because it is in close contact with liquid water below.

Theory is still struggling to keep pace with the flood of new data, but a picture of Europa as a world dominated by the tides and torques of Jupiter is emerging from the Galileo observations. Europa's tidal bulges wax and wane with an 85 h period owing to the changing distance between the moon and the planet, and also rock back and forth as they try to track Jupiter. As a result, the solid ice shell is subjected to stresses that change with both time and location as the shell stretches to accommodate Europa's changing figure. One consequence of this tidal flexing is that any cracks that penetrate through the shell to a liquid layer below will be pulled apart and slammed shut again each 85 h Europan 'day', providing a possible mechanism for building the satellite's unique ridge pairs. In some locations, the daily cycle starts as the fractures open and then the two sides begin to shear past one another in a transverse sense. Later in the day the stresses reverse, closing the cracks and favoring transverse motion in the opposite direction. This reverse shear is ineffective, however, since the cracks are under compression during this part of the cycle. The net effect is to ratchet the sides of the cracks past one another, forming strike-slip faults with mainly left-lateral displacements in the northern hemisphere and an opposite sense of motion in the south, just as observed. The most prominent example of this process on Europa may be Astypalaea Linea, an enormous strike-slip feature that rivals the San Andreas fault on Earth. The strange cycloidal lineaments are also thought to be due to the daily tides: a slowly opening crack should follow a curvilinear path across the surface as it tracks the changing tensional stress throughout the day, but the propagation ceases during the period when the local stress becomes compressional instead. Crack propagation resumes the next day when the stresses are again tensional, but by then the orientation of the local stress field has changed and the crack sets off in a new direction. The cusps of the cycloids, in this model, are the places where the crack propagation paused during the formation of these odd features.

Another consequence of Europa's eccentric orbit is that Jupiter exerts a torque on the satellite that makes Europa (or at least its outer shell) spin at a rate slightly faster than it orbits. As a result, the surface of the moon gradually shifts eastwards with respect to Jupiter over geological time. Europa's non-synchronous rotation is too slow to be measured directly, but it has left its mark on the landscape. Galileo has explored several locations where successive generations of lineaments overprint their predecessors at oblique angles, indicating systematic rotation of the local stress fields. The sense of rotation is clockwise in the northern hemisphere and anticlockwise in the south, consistent with the predictions of theory. The ice shell should stretch as it shifts over the tidal bulges, and indeed a zone of crustal extension is seen to the west of the anti-Jupiter point. (The Jupiter-facing side of Europa, where such extension is also predicted to occur, has not yet been seen as of this writing.) The model also explains why some fractures may be dormant for extended periods and reactivated later when relocated to more favorable longitudes.

These theoretical arguments, if correct, imply the existence of a subsurface liquid layer in order to raise tides sufficient to fracture the ice shell and to decouple the crust from the rocky interior and allow it to rotate freely. Together with the evidence of localized heating and the suspected infall of organic materials from such sources as comets, the possibility of an ocean on Europa could have profound significance to the search for extraterrestrial life. Recognizing this, NASA is developing a mission specifically designed to determine whether or not a subsurface sea exists on Europa. The Europa Orbiter spacecraft will directly detect any extensive ocean by taking the 'pulse' of the satellite (measuring its tidal amplitude using gravimetry and altimetry) and sounding the subsurface with radar and will also produce a global map of this intriguing moon and search for suitable landing sites and signs of present-day activity.

Ganymede

Ganymede is the largest Galilean satellite and indeed the largest moon in the solar system. It is slightly bigger than Mercury, and would be considered a planet in its own right if not for the fact that it is in orbit about a larger world. Its interior is strongly differentiated into an iron-rich core, a silicate mantle and an icy crust much thicker than Europa's. Close flybys of Ganymede by the Galileo spacecraft revealed an intrinsic magnetic field with a strength about 1% of Earth's, suggesting that the satellite's iron core is still molten. Hence we suspect that core formation may have taken place relatively recently, perhaps triggered by tidal heating within the last billion years or so. Such tidal heating is negligible today, but Ganymede may have passed through periods of intense heating as its orbit evolved prior to being captured into its present stable resonance with Europa and Io. During differentiation, the H_2O and CO_2 ices buried deep within Ganymede floated up towards the surface, displaced by the heavier silicates and metal sinking into the interior. Water ice should have expanded as it decompressed and converted from higher-density phases into its familiar hexagonal form. The volume of the satellite would have increased as a consequence and the resulting global expansion probably split Ganymede's surface, replacing some of the ancient crust with lanes of younger material. This tumultuous history seems to be reflected in the geology of the satellite's surface.

Ganymede's crust is divided into two major terrain types. Older areas such as Galileo Regio are dark and heavily cratered and may represent the moon's primordial surface. Few tectonic features are found on these ancient terrains other than vague furrows probably formed by giant impacts. Craters on Ganymede display a remarkable diversity ranging from simple bowl shapes similar to their lunar counterparts, through flat-floored basins with curious central pits and domes, to ancient, flat circular structures called palimpsests that are scarcely recognizable as impact features and evidently formed while the moon's interior was still warm and ductile. A few scalloped depressions in the ancient terrain may indicate early outpourings of liquids from the interior, the watery equivalent of volcanic magmas. Ganymede's younger regions, in contrast, are brighter and show signs of intense tectonic deformation. These younger areas consist of narrow lanes of 'grooved terrain' tens of km wide and hundreds of km in length. Once suspected to be of volcanic origin, the grooved terrains were seen in closeup Galileo pictures to consist of closely spaced domino-style faults and graben indicative of crustal extension. At least two scales of tectonic deformation can be recognized in these regions: fine fractures spaced a few hundred meters apart, indicating brittle failure of the cold surface, are superimposed on broad undulations with wavelengths of several km, probably produced by ductile necking of the crust.

Ganymede's high latitudes are decorated by bright frosty polar caps. These frosts are concentrated on the slopes that face away from the Sun and are probably derived from ice that sublimated away from the warmer equatorial areas. The polar regions may also be brightened by charged particles that spiral inwards along magnetic field lines and stir up the surface on impact. Charged particles are probably responsible for Ganymede's faint oxygen aurorae, observed near the poles at ultraviolet wavelengths. Ganymede's tenuous atmosphere is made up mostly of hydrogen atoms flowing rapidly away from the moon, amounting to a total loss of millions of kg per year. The hydrogen gas is probably derived from the dissociation of water ice on the surface of the satellite by charged particles and solar ultraviolet photons. The light H escapes, while the heavier O is left behind to form strong oxidants such as molecular oxygen, ozone and hydrogen peroxide. Ganymede's older regions are tinged by a dark non-ice contaminant that is distinct in color from Europa's enigmatic red-brown stains but similar in appearance to Callisto.

Callisto

Only one of the Galilean satellites retains a surface unmodified by internal geological activity. Callisto appears to have passively recorded a history of bombardment by impactors. Unlike Io, Europa and Ganymede, Callisto is not trapped in an orbital resonance with its neighbors that forces tidal heating. Galileo gravity measurements indicate that Callisto's interior is only slightly differentiated, largely unchanged from its initial accretionary mixture of rock and ice. Nevertheless, Galileo's magnetometer recorded an induced magnetic signature from the satellite indicating the presence of an electrically conducting layer not far below the surface, such as subterranean brines. Callisto's dark, battered surface is similar to the older terrains on Ganymede. Several of the latest large impacts took place on Callisto's orbital leading side. The greatest was Valhalla, which produced a palimpsest 600 km in diameter and a set of rings that nearly encircle an entire hemisphere. More recent impacts excavated bright, relatively clean ice from beneath the surface. Paradoxically, at subkilometer scales there are far fewer craters on Callisto than Ganymede. High-resolution pictures of Callisto show a smooth blanket of dark material instead of the pock-marked landscape expected from more distant vistas. Sublimation of CO_2 and H_2O ices may be responsible for the dearth of small craters on Callisto. In many places the landscape appears to have been degraded by sublimation, leaving behind a lag of dark non-ice material that fills the topographic lows. The icy rims of several small craters have eroded into isolated knobs, while pits have been produced in other places by the removal of ice. Some initially circular craters have been deformed into irregular depressions, and several landslides of dark lag material extend from

the less stable slopes of the eroding crater rims. The dark mantling material may have an external origin, perhaps deposited by impactors or debris that drifted inwards from the outer satellites.

Outer satellites

Little is known about the eight small moons that orbit beyond Callisto. At present even their sizes can be only roughly estimated, pending knowledge of their reflectivities. Their orbits fall into two groups, both at odds with Jupiter's rotation (figure 3). The innermost family (Leda, Himalia, Lysithea and Elara; names ending with the letter 'a') have dynamically young, prograde orbits that are steeply inclined with respect to Jupiter's equatorial plane (table 1). The outer family (Ananke, Carme, Pasiphae and Sinopë; ending with 'e') orbit in the retrograde direction, opposite to Jupiter's rotation, and are so far away from Jupiter that their paths are strongly perturbed by the gravity of the Sun. All of these satellites are dark, reddish objects that could conceivably contribute to the coloration of Callisto and Ganymede, dusting the icy moons with debris derived from impacts. No spectral features diagnostic of their composition have yet been recognized on these satellites. The outer family satellites are somewhat redder than the inner group, similar to the colors of the TROJAN ASTEROIDS. The distant Trojans are also gravitationally trapped by Jupiter, in stable points ahead of and behind Jupiter as it orbits about the Sun. The ranges of rotation periods and shapes (lightcurve amplitudes) of the satellites are similar to those of Trojan and main belt asteroids, suggesting comparable collisional histories.

These two satellite families may be the fragments of larger parent bodies that shattered when they were gravitationally captured by Jupiter. A vivid example of one such disruption was displayed recently by comet Shoemaker–Levy 9 when it ventured too near Jupiter and was torn to pieces by the tides (see SHOEMAKER–LEVY 9–JUPITER COLLISION). Much more violent forces are expected in the case of a satellite captured by gas drag after colliding with Jupiter's atmosphere or protoplanetary nebula. Such forces are capable of disrupting much stronger and larger objects like the parent bodies of the outer satellites. Perhaps some of the Pasiphae family fragments leaked out of the Jupiter system during the upheaval: the Trojans could be rogue satellites that escaped from Jupiter and were later recaptured. Evidence of past episodes of capture and catastrophic disruption can be seen on the surface of Callisto, which bears the scars of several impacts by Shoemaker–Levy 9-like objects as linear chains of impact craters found on the Jupiter-facing hemisphere.

Web update (30 April 2003)

Recent results from the Galileo spacecraft reveal Jupiter's inner moon, Amalthea, has a very low density. Amalthea is apparently a loosely packed pile of rubble. The empty gaps between solid chunks likely take up more of the moon's total volume than the solid pieces, and even the chunks are probably material that is not dense enough to fit some theories about the origin of Jupiter's moons. Amalthea now seems more likely to be mostly rock with maybe a little ice, rather than a denser mix of rock and iron.

Kant, Immanuel (1724–1804)

German philosopher, born in Königsberg, published his view of the universe in *General History of Nature and Theory of the Heavens* (1755) in which he presented his nebular hypothesis of the formation of the solar system. It was much like the present theory that the Sun and planets formed from the condensation of a rotating disc of interstellar material. Kant identified the Milky Way as a lens-shaped collection of stars in orbit around its center like the rings of Saturn, and as one of many 'island universes' (he coined the term). He suggested that the tides raised by the Moon were the reason why the Moon always presented the same face towards us, and that tidal friction was slowing the rotation of the Earth. Kant's philosophy is described in *Critique of Pure Reason*.

Kanzelhöhe Solar Observatory

The Kanzelhöhe Solar Observatory was founded during World War II and belongs to the Institute of Astronomy of the University of Graz. The site is located at 1400 m altitude near Villach in Austria and is very well suited for long-term studies of the Sun. Therefore it was selected as the only ground-based support observatory in Central Europe for satellite missions (SOHO). With a newly installed magneto-optical filter, high time cadences of solar magnetograms can be obtained. Sunspot numbers and flare patrols are submitted to the scientific community.

Kapteyn Astronomical Institute

The Kapteyn Astronomical Institute, University of Groningen, the Netherlands, specializes in the areas of structure of galaxies and the universe and interactions between stars and the interstellar medium, using many national and international observing facilities all over the electromagnetic spectrum. Specific areas of research include the distribution and nature of dark matter in galaxies, gravitational lenses, molecular astrophysics and the large-scale structure of the universe.

The Kapteyn Institute is located at the university campus (Zernike complex) on the outskirts of the city of Groningen in the northern part of the Netherlands. It was founded at the end of the eighteenth century by Jacobus Kapteyn as an 'astronomical laboratory', where plates taken elsewhere were measured and analysed. Kapteyn is the founder of modern research on galactic structure through star counts and the father of the famous 'Plan of Selected Areas'.

The Institute currently has about fifteen permanent scientific staff members and eight support personnel and on average about five postdoctoral fellows and twenty graduate students working on their PhD theses. In addition there are about fifty undergraduate students in astronomy. Funding comes mostly from the university with additional positions for temporary appointments (postdoctorates and graduate students) from the Netherlands Organization for Scientific Research NWO (the Research Council) and international funds such as from the European Commission.

The Kapteyn Institute is part of the Netherlands Graduate School on Astronomy (NOVA) together with the three other major astronomy institutes at the universities of Amsterdam, Leiden and Utrecht. The Kapteyn Institute shares its building with part of the Netherlands Foundation for Space Research (SRON), which is funded by NWO and specializes in the building of instrumentation for astrophysical space facilities.

Research at the Institute covers a broad range of topics, ranging from molecular astrophysics of the interstellar medium, late stages of stellar evolution, structure and dynamics of galaxies to large-scale structure of the universe. A major highlight of the work at the Institute concerns the distribution and nature of dark matter in galaxies, first through the observations of the rotation in spiral galaxies using the 12 cm spectral line of neutral hydrogen on the Westerbork Synthesis Radio Telescope and currently, at an increasing level, using various forms of gravitational lensing.

Research facilities are all on the basis of national and international levels. On the Earth these include the WESTERBORK SYNTHESIS RADIO TELESCOPE and the associated European Network for Very Long Baseline Interferometry, the (UK–NL–Canada) JAMES CLERK MAXWELL TELESCOPE at millimeter wavelengths, optical and near-infrared facilties at the UK–NL ISAAC NEWTON GROUP OF TELESCOPES at La Palma, Canary Islands and the EUROPEAN SOUTHERN OBSERVATORY in Chile. Through SRON and ESA, access is provided by a whole range of space facilities, of which the Hubble Space Telesope and the ESO Infrared Space Observatory (ISO) mission are currently the most important.

Kapteyn, Jacobus Cornelius (1851–1922)

Dutch astronomer, who, at the University of Groningen, and with the aid of convicts from a prison nearby, measured photographic plates taken by DAVID GILL at the Cape of Good Hope. He compiled a catalog of half a million southern stars, from which he derived values for the density of stars in space as a function of distance, brightness and spectral class, extending Herschel's work (see HERSCHEL FAMILY). In the *Kapteyn model* of the Galaxy, he confirmed that the Galaxy was lens-shaped. However, his conclusion that the Sun was located near the center was an error caused by interstellar absorption which limited the distance that he could sample, in the same way that someone in a fog could believe there was nothing outside the circle that he could survey. Kapteyn went on to identify Selected Areas, in which he proposed that astronomers worldwide sample the faint stars and thus map the Galaxy. This project was undermined by the First World War, and was perhaps too big to be completed even in peacetime, but stimulated many individual discoveries. He measured the velocities of stars and discovered 'star streaming', which proved to be a manifestation of the rotation of the Galaxy. He discovered *Kapteyn's star*, which has the second largest proper motion after BARNARD's star. He successfully explained the expanding halo around Nova Persei, discovered by CHARLES DILLON PERRINE as a light echo, reflecting the nova flash from surrounding dust clouds. The *Kapteyn telescope* on La Palma is named after him.

Kapteyn's Star

A faint red dwarf star (apparent magnitude 8.86, spectral type M0V), situated in the southern constellation of Pictor, about 12″ north-west of Canopus. Discovered by the Dutch astronomer Jacobus Kapteyn (1851–1922) in 1897, it is notable for having the second largest proper motion known: its motion of 8.67″ per annum is exceeded only by that of Barnard's Star. It is also one of the closest stars to the Sun: 12.8 light-years distant, it has a parallax of 0.255″ and its absolute magnitude is 10.9.

Keeler, James Edward (1857–1900)

Astronomer, born in La Salle, IL. In 1881 went with a pack train of mules, loaded with mirrors, telescopes and bolometers, to the 14 495 foot summit of Mount Whitney, California (the highest elevation in the contiguous United States), to measure, undisturbed by the atmosphere, the infrared spectrum of the Sun and its flux, the 'solar constant'. Became director of the Allegheny and Lick observatories, established that Saturn's rings were not solid by showing that they rotated with motions which conformed to KEPLER's law (as JAMES CLERK MAXWELL had predicted), implying that they consisted of meteoric particles in individual orbits. Founded the *Astrophysical Journal* in 1895 with GEORGE E HALE, in the first volume of which Keeler's paper on Saturn's rings appeared the month after he had taken the spectra!

Kepler

Johannes Kepler (1571–1630) was arguably the most innovative astronomical theorist in the millennium and a half from Claudius PTOLEMY's *Almagest* (c. AD 150) to Isaac NEWTON's *Principia* (1687). Before Kepler, planetary and lunar theory had consisted in combining circular motions, either strictly uniform or angularly uniform about an off-center 'equant' point, so as to 'save the appearances'. The planets were taken to be perfect beings for whom the only thinkable motion was circular. Kepler changed all this by envisaging planets and satellites as bodies moving in orbits under the action of forces issuing from the central body. In the detailed working out of this dynamical conception, he arrived, with the crucial help of TYCHO BRAHE's astronomical observations, and inspiration from WILLIAM GILBERT's magnetic philosophy, at the rules for which he is famous: elliptical paths, each radius vector from Sun to planet sweeping out equal areas in equal times, with the periodic times of the several planets proportional to the 3/2 power of their mean solar distances.

Since the eighteenth century these rules have been called 'laws'. Were they empirical laws, verified with a specifiable precision? The truth is more complicated and more interesting. Kepler's revolution can rightly be understood only in its historical context, with careful attention to his processes.

Copernicanism

From 1589 to 1594 Kepler attended the University of Tübingen, aiming to become a Lutheran pastor. An eager student, he ranged widely through the approved learning of his time. In theology he found the Lutheran doctrines of the bondage of the will and the Real Presence in the Eucharist indigestible, but kept his doubts to himself. He was attracted to Neoplatonic symbolism and to the writings of NICHOLAS OF CUSA. Through the teaching of MICHAEL MÄSTLIN, professor of mathematics and astronomy, he became enamored of Copernicus's heliocentric astronomy, though without access as yet to Copernicus's *The Revolutions of the Heavenly Spheres* (1543). The Tübingen theological faculty had prohibited the teaching of heliocentric astronomy as contrary to Holy Writ, but Mästlin privately helped a few exceptional students like Kepler to understand the kinematic economy of the heliocentric arrangement.

Copernicus's *Revolutions* had been published with a preface asserting the hypotheses of the work to be merely devices for accommodating the phenomena. This 'positivist' preface, not in fact by NICOLAUS COPERNICUS but by ANDREAS OSIANDER who had guided the book through the press, expressed a widely accepted view of astronomical hypotheses. The COPERNICAN SYSTEM contradicted both the literal sense of Scripture and the accepted theory of projectile motion. The kinematic economy of this system could be achieved otherwise, by the 'geoheliocentric' arrangement, in which the Earth remained at rest with the Moon and Sun circling about it, and the remaining five planets circled about the Sun. Tycho Brahe was the leading proponent of this alternative system.

Meanwhile, Copernicus got high marks for something separate from his heliocentrism: the replacement of Ptolemy's equant point by an epicyclic mechanism. The equant, according to Copernicus, by making motion on the circle non-uniform, violated a first principle of the astronomer's art. His insistence on strictly uniform circular motions in astronomical theory was accepted by many late sixteenth-century astronomers, including Tycho.

Kepler in his student days had not yet faced the difficulties of a detailed fitting of astronomical theory to observational data. What attracted him so powerfully to heliocentrism was the theological symbolism he saw in it. Nicholas of Cusa had portrayed the circle as an image of the Trinity: God the Father at the center, the Son at the periphery, the Holy Spirit in the relationship of center to periphery. For Kepler this Trinitarian image expanded to include the whole spherical world, with the Sun at the center and the stars at the periphery reflecting back the solar light. God in creating the world had created an image of Himself, and had placed the contemplative creature Man (also created in His image) on a moving planet, that he might, by calculating for his own displacement, discern the beautiful layout of the world. As Kepler later put it, travel is broadening.

The cosmographic mystery

Early in 1594 the position of mathematics teacher at a Protestant boys' school in Graz, Austria, fell vacant, and the senate of the University of Tübingen, asked to recommend a successor, chose the mathematically talented Kepler. This summons perturbed Kepler; he accepted it only with the proviso that he might later return to complete his theological studies.

While teaching at Graz, Kepler made an astronomical discovery that brought renown and confirmed him in an astronomical career. He had been persistently seeking, he tells us, the causes of three things: the number of the planets, their distances from the Sun, and the periods of their motions. Euclid in his *Elements* demonstrates that there are just five regular convex polyhedra: cube, tetrahedron, dodecahedron, icosahedron and octahedron. Let spheres be circumscribed about and inscribed within each of these, and let these spheres be nested so that the in-sphere of one polyhedron is the circum-sphere of the next; then there will be six spheres in all, just as many as there are planets in the Copernican system. Moreover, if the polyhedra are taken in the order just given (and Kepler provided an *a priori* explanation for this order), then the radii of the spheres prove to be in astonishingly close agreement with the radii of the planetary orbits. Uncertainty remained as to the exact values of the orbital eccentricities, and therefore as to the thickness to be assigned to each sphere. Nevertheless, Kepler's discovery of an *a priori* derivation of the number and distances of the planets impressed his teacher Mästlin, who helped him in preparing an account of it: the *Cosmographic Mystery*,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

published in March 1597. Kepler sent a copy to Tycho Brahe.

The polyhedral hypothesis was a formal or aesthetic cause, plausible to Kepler because he believed that God in creating the world had made it beautiful for the delectation of the contemplative creature, Man. In the *Cosmographic Mystery* Kepler also considered the *efficient cause* of the planetary motions. He hypothesized it to be a moving soul (*anima motrix*) situated in the Sun, the efficacy of its causal action diminishing with distance. In confirmation whereof he showed that average linear speed was less for planets farther from the Sun, and the linear speed of each individual planet diminished as its solar distance increased. Kepler did not have our principle of inertia; he was assuming that speed was proportional to force, and that an immaterial virtue, issuing from the Sun and rotating with it, pushed the planets about.

Meanwhile the Counter Reformation came to Inner Austria. In September 1598 the Protestant school in Graz was closed down and most Protestants were exiled. Kepler remained as district mathematician until August, 1600, when he too was exiled for refusing to convert to Catholicism. Earlier in 1600 he had visited Tycho in Bohemia and agreed to assist him in preparing his works for publication. In October 1600 he arrived in Prague with his family, his future now totally dependent upon Tycho's goodwill and sponsorship. In September 1601 he was granted a stipend by the Emperor Rudolph II to collaborate with Tycho in assembling new planetary tables. On 24 October Tycho died, and two days later Kepler was appointed imperial mathematician in Tycho's place. The 10 succeeding years in Prague would be among the most fruitful of his life.

The Optical Part of Astronomy and *The New Astronomy*

Kepler's *The Optical Part of Astronomy* (1604) contained major new results for both optics and astronomy: the geometrical explanation of the formation of images through small apertures, as in the *camera obscura* (used in the observation of solar eclipses); the most accurate table of astronomical refractions yet to appear, based on a law of refraction closely approximating the sine law; the first enunciation of the inverse-square law for the intensity of illumination from a point source; the discovery of the formation of inverted images on the retina of the eye. In planetary theory the revolutionary work was Kepler's *New Astronomy* (1609), a study of the motions of Mars.

This book has the form of a narrative tracing Kepler's journey in arriving at the elliptical orbit and area rule, but it is not strict history; Kepler used the narrative form in an effort to disarm hostile critics and persuade astronomers discomfited by the new ideas. Throughout he was guided by the conception of the Sun's dynamical role as articulated in the *Cosmographic Mystery*. From this conception came his hypothesis that the orbit of Mars lay in a plane passing through the Sun's center, with a constant inclination to the ecliptic; the complicated theories of the latitudes in earlier astronomy were thereby replaced by a simple, accurate predictive scheme. All earlier astronomers had reckoned the orbital eccentricities of the planets from the midpoint of the Earth's orbit (the 'mean Sun'), or in geocentric terms from the Earth's center; Kepler wanted the eccentricities to be reckoned from the true Sun, and showed that observational data were not opposed. His further study of Mars's motion in longitude yielded yet more innovative results.

To know Mars's motion about the Sun it was necessary to start from observations of Mars in opposition to the Sun, when the planet's longitude as seen from the Earth is also its heliocentric longitude. Kepler had twelve such observations to work with, ten made by Tycho, two by himself. He assumed a circular path for the planet and an equant point, then by trial and error so determined the solar distances of the equant point and circle's center as to obtain the best fit to four of the observed longitudes. With the circle's radius as unit, the solar distance of the circle's center proved to be 0.11332, and that of the equant 0.18564. Then he compared the theory's predictions with all twelve observations. The largest deviation was $2'12''$; the average deviation, $51''$. The theory's predictions were thus as accurate as the observations, but as Kepler next showed, it was false. He called it his 'Vicarious Theory': not the true theory, but accurately predicting Mars' heliocentric longitudes.

The theory was disproved by two sorts of observation of Mars near perihelion and near aphelion: Mars' latitudes when in opposition, and its longitudes when Mars, Earth and Sun were no longer aligned. From the triangles involved he calculated Mars's solar distances at aphelion and perihelion in terms of the Earth–Sun distance as unit. The midpoint of the line from perihelion to aphelion proved to be just halfway between the Sun and equant point, not 0.61 of the way as in the Vicarious Theory. If he altered the Vicarious Theory to agree with this 'bisection of the eccentricity', the altered theory erred by about $8'$ in the 'octants' (at 45° from aphelion or perihelion).

No equant theory, he concluded, and hence no Copernican epicyclic replacement for an equant theory, could yield true predictions where the orbital eccentricity was large. Therefore, Kepler argued, it was justifiable to resort to physics. Bisection of the eccentricity implies an inverse proportionality of speed to solar distance in the apsidal line. Was it not then the Sun's virtue that moved the planets in their paths, with a strength that fell off with distance?

Kepler actually spoke not of speeds but of 'delays' (*morae*). Assuming these to be proportional to solar distance, he undertook to allot times to each degree in the semicircle from aphelion to perihelion so that the times would add up to a half period. The area rule first emerged as a short cut: all the solar distances are contained in the areas swept out, so let the times be as these areas. Years later (in his *Epitome of Copernican Astronomy*, 1621) he would show that this rule meant an inverse proportionality of distance with the *component* of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the planet's speed at right angles to the radius vector. In the *New Astronomy* his justification of the rule remained confused.

Applying the area rule to the circular orbit, Kepler found it put the planet 8′ ahead at 45° from aphelion, and 8′ behind at 135° from aphelion: if area meant time, there was too much area in the middle longitudes. By triangulation Kepler verified that, indeed, the orbit came within the circle in the middle longitudes; it was oval. Concocting an epicyclic theory that yielded an oval orbit, he found the opposite kind of error: −8′ at 45°, +8′ at 135°. An elliptical orbit halving the difference would be just right. But why should the planet move in such an orbit?

An explanation had to be found for the planet's changing its solar distance. Kepler's ultimate hypothesis was a quasi-magnetic mechanism in which the Sun's surface was one pole of a magnet, and the two poles of the planet caused it to be alternately attracted and repelled, so as to librate sinusoidally along the radius vector. At first he imagined the orbit resulting from the libration would be 'puffy-cheeked', differing from the ellipse of the previous paragraph. In chapter 58 he claimed to refute the puffy-cheeked orbit from observation, and then reported that the libration and the ellipse could be made to agree, concluding that the orbit could only be a perfect ellipse. The latter statement has often been repeated by commentators. But Kepler's empirical refutation of the puffy-cheeked orbit is obscure and cannot be right. His claim to have excluded all alternatives to the ellipse cannot stand.

What was important for astronomy's future, however, was that Kepler's combination of ellipse and area rule led to the *Rudolphine Tables* (1627), planetary and lunar tables more accurate than any produced before. Kepler's *ephemerides* (daily positions), published for the years from 1617 to 1637, helped win converts to his tables. Not that Kepler's hypothetical mechanisms, or his area rule, gained a following: astronomers publishing tables in mid-century—chiefly Ismael Boulliau, Vincent Wing and Thomas Street—used substitutes for the area rule that were computationally more convenient, while recognizing that they must nearly duplicate Kepler's numbers. The elliptical orbit came to be widely accepted.

Kepler's harmonic law

Kepler discovered his 'third' or 'harmonic law' in May 1618, and announced it, without supplying empirical evidence, in his *Harmonic of the World* (1619). This latter work is Kepler's final account of the geometrical harmonies adorning God's creation. In Book IV of the *Epitome of Copernican Astronomy* (1621) he derived the harmonic law from efficient causes, assuming his pre-inertial dynamics plus monotonic variations of the volumes and densities of the planets with solar distance. By the 1630s, empirical evidence from improved telescopes had shown the monotonic variation of volume with distance to be untenable. In Kepler's *Rudolphine Tables* the planetary distances were not in strict accordance with the harmonic law; the first to make them so was JEREMIAH HORROCKS (1618?–41), and Thomas Streete followed this Horrocksian practice in his *Astronomia Carolina* (1661), from which Isaac Newton learned of it.

Kepler's other harmonic speculations were of no influence in later astronomy, yet have a certain kinship with supersymmetry and the anthropic principle in recent physics and cosmology.

The sorrows and difficulties of Kepler's last 18 years—deaths of a wife and children, money problems, excommunication from the Lutheran Church, trial of his mother for witchcraft, etc—can only increase our wonder in his remarkable journey of discovery.

Kepler's Laws

Johannes KEPLER published his three laws in 1609 and 1618 (table 1). Based on the very precise observations of Mars' orbit made by Tycho Brahe, and developed in the Copernican system, they describe the shape of the orbit of the planets around the Sun as an ellipse (first law), explain how the planets move around the Sun (second law) and give a relationship between the extent of the orbit and its period (third law).

Historically, these laws represented a strong and original improvement compared with the complicated system of epicycles derived by PTOLEMY. They permitted the calculation of much more precise astronomical tables. Furthermore, they introduced a revolutionary concept: a physical phenomenon can be simply expressed by a mathematical equation. Johannes Kepler stated his laws, which did not explain the physical cause of the trajectories and movements of the planets, before GALILEO GALILEI's and Isaac NEWTON's work. Actually, Kepler's laws can be inferred from Newton's laws. They apply in fact to any system including two objects in close gravitational interaction so that other gravitational fields can be neglected. That is the case for the solar system, dominated by a central massive object surrounded by smaller ones. When transposed to binary stars, to extrasolar systems or to any pairs of objects obeying the two-body interaction, the third law allows us to determine the total mass of the system. This point has therefore crucial consequences: the third law is a universal scale that makes it possible to remotely measure the mass of objects in the universe.

The physical content of Kepler's laws is explained first. For sake of simplicity, the solar system, to which Kepler applied his laws, is chosen as the standard case. Other systems are also considered, when the third law is examined. Kepler's life and ideas are then jointly presented, in order to demonstrate the major steps of his work. The revolutionary ideas he introduced are compared with the previously existing astronomical systems. Finally, the physical content of the laws is examined according to the concept of integral quantities, and their limitation is presented.

Table 1. Definition.

- First law: the path of each planet around the Sun is an ellipse, with the Sun at one of the foci
- Second law: each planet moves in such a way along its orbit that a line drawn from the Sun to the planet sweeps equal area in equal amount of time
- Third law: the ratio of the cube of the semimajor axis of orbit to the square of the orbital period is the same for all planets

Kepler's three laws

Kepler's first law

- The path of each planet around the Sun is an ellipse, with the Sun at one of the foci.

Kepler's first law, purely geometric, describes the shape of the orbit as a very simple figure: the ellipse (table 2). An ellipse being a plane figure, this already constitutes a remarkable result. Thanks to TYCHO BRAHE's observations, Kepler proved that planets moving in three-dimensional space follow a path included in a fixed plane. Astronomers before him only supposed this fact. Furthermore, Kepler was able to exhibit the exact shape of the trajectory as well as the role of the Sun. The Sun occupies one of the foci of the ellipse, the other focus and the center of the ellipse playing absolutely no part. According to the predominating position of the Sun, this first law confirmed the relevance of the COPERNICAN SYSTEM.

The elliptical shape summarized the complicated and *ad hoc* accumulation of epicycles invented by the Greeks: in the trajectory plane, three orbital elements are enough to define an ellipse. The semimajor axis a and the eccentricity e give the extent and the oblateness of the trajectory (figure 1, figure 2, table 3); the direction of the major axis of the ellipse is determined by a further constant.

Kepler's first law, when defining the trajectory of a planet, remains, however, incomplete. The trajectory gives all the possible positions, but no time indications. The time dependence, crucial for the construction of astronomical ephemerides predicting the planetary positions, is given by the second law.

Table 2. Conic sections.

Eccentricity	Conic section
$e = 0$	Circle
$0 < e < 1$	Ellipse
$e = 1$	Parabola
$e > 1$	Hyperbola

The orbit of an object in the gravitational field of another object is a conic section. The general mathematical form of conic trajectories expressed in polar coordinates (r,θ) is $r = p/(1 + e \cos \theta)$, with p the parameter of the conic section and e its eccentricity (see figure 7). The nature of the conic section depends on the value of the eccentricity.
The trajectories of the eight planets of the solar system are nearly circular. The closest point to the Sun is the perihelion and the farthest the aphelion. Perihelion and aphelion, aligned with the focus, define the line of apses, or major axis. They are separated by a distance $2a$, a being the semimajor axis, related to the parameter p and eccentricity e by $a = p/(1 - e^2)$ (figure 2).

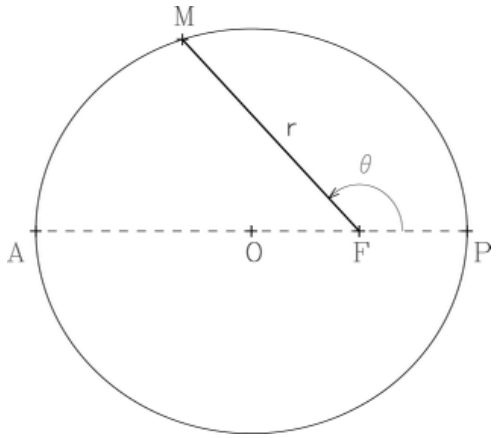

Figure 1. The trajectory of orbiting objects around the Sun is an ellipse, the Sun being located at one of the foci. The semimajor axis *a* is half of the distance between perihelion P and aphelion A; the distance between the center O and the focus F defines the eccentricity *e*: OF = *ae*. When considering objects orbiting the Earth, the closest and farthest points are respectively the perigee and apogee, and pericenter or apocenter in the general case. Small bodies in the solar system have usually greater eccentricities than the planets. For comets, the value of *e* is often very close to 1.

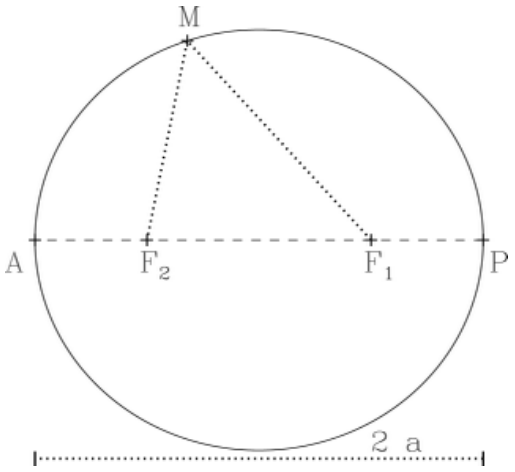

Figure 2. The sum of the distances between a given point of the ellipse and the two foci is constant and equal to 2*a*.

Kepler's second law

- Each planet moves in such a way along its orbit that a line drawn from the Sun to the planet sweeps an equal area in an equal amount of time.

The second law does not introduce the time dependence in a simple way, since, except in the particular case of a circular path, the position along the orbit cannot be expressed explicitly. It was therefore necessary for Kepler to consider not the position of the planet, but the area swept by the position vector around the Sun, in order to show that this area increases linearly with time (figure 3). The first step was to identify that a planet moves faster when closer to the Sun. The precise expression of this second law was carefully derived from the analysis of a very large amount of data concerning the position of Mars. In the first published version of this law, the discovery of the equal-area law was first derived from two false steps that by chance cancelled each other. Much later, Kepler gave an exact demonstration.

In fact, this second law establishes the possibility of astronomical prediction: it makes it possible to follow step by step the progression of a planet along its orbit. According to his first and second laws, Kepler constructed timetables for the planets, which were used for more than one century. They were much more precise than the astronomical tables based on the PTOLEMAIC SYSTEM. For the first time, predictions concerning the declinations of the planets were made possible (actually, the Ptolemaic system was unable to predict the declinations of the planets). More than the novelty of the approach, the accuracy of the predictions ensured the success of Kepler's laws.

Kepler's third law

- The ratio of the cube of the semimajor axis of orbit to the square of the orbital period is the same for all planets.

This third law introduces another concept compared with the two previous ones, which are restricted to one single object around the Sun. It gives a relation valid for all the objects orbiting the Sun. Kepler discovered the relation between the semimajor axis *a* of the orbit and the sidereal period *T*. The ratio T^2/a^3 is constant for all objects in the solar system orbiting the Sun (table 4). The introduction of sidereal rotation periods gave another argument in favor of a heliocentric view of the solar system, since sidereal periods are corrected for the Earth's motion.

Table 3. Orbital elements.

The complete description of a planetary orbit results from six integration constants. These constants can be, for a numerical approach, the initial values of the radius and velocity vectors. In terms of integral quantities, one defines the angular momentum σ and eccentricity vectors ***e***, plus the perihelion time. For a geometric view of the problems, one defines six orbital elements:
• semimajor axis *a*
• eccentricity *e*
• inclination *i* compared with the ecliptic
• longitude of the ascending node Ω (the lines of nodes is at intersection of the ecliptic plane and the planetary orbital plane)
• argument of the perihelion ω
• time of the perihelion τ

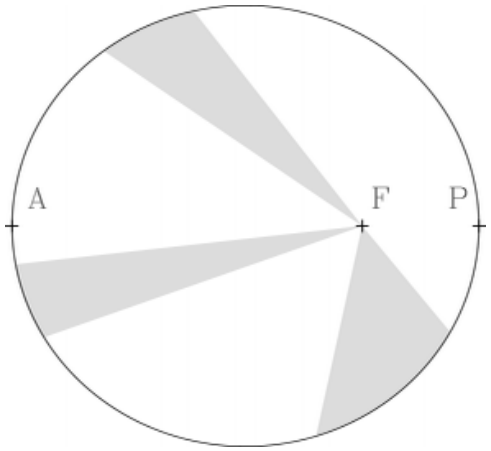

Figure 3. The body orbiting around the Sun moves in such a way that equal areas are swept out in equal amounts of time. This relation implies that the velocity decreases with increasing distance to the Sun. The maximum velocity is reached at perihelion, and the minimum one at aphelion.

Table 4. Semimajor axis and eccentricity.

Planet	a (AU)	T (yr)	e
Mercury	0.3871	0.2408	0.2061
Venus	0.7233	0.6152	0.0068
Earth	1.0000	1.0000	0.0167
Mars	1.5237	1.8809	0.0934
Jupiter	5.2026	11.862	0.0483
Saturn	9.5547	29.458	0.0560
Uranus	19.2181	84.010	0.0461
Neptune	30.1096	164.79	0.0097

The precision of the measurements of the semimajor axis a and the revolution period T is in fact limited by the planetary interactions perturbing the central solar gravitational field. With a in astronomical units and T in years, the ratio T^2/a^3 is very close to 1 for all inner planets whose masses are negligible compared with the solar mass. It is about 0.999 for Jupiter, since the mass of this planet represents one-thousandth of the solar mass, and around 0.995 for the other outer planets, owing to perturbations.

Kepler's work did not explain the physical reason for this law. The inverse square law of gravitation discovered by Isaac Newton shows that the ratio T^2/a^3 is determined by the mass of the Sun. The exact formula introduces the total mass of the system, including the mass of the planet, which is in fact negligible compared with the mass of the Sun.

The mathematical expression of Kepler's third law becomes very simple provided that the semi-major axis is expressed in astronomical units and the orbital period in years. One astronomical unit (1 AU) represents by definition the semimajor axis of the Earth's orbit ($1.495\,978\,7 \times 10^{11}$ m). Within this unit system, Kepler's third law becomes, for any object belonging to the solar system,

$$\frac{T^2}{a^3} = 1.$$

This relation allows us to determine the semimajor axis of the orbit, knowing its period, or vice versa. For example, the sidereal period of comet Halley being 76 yr on average, its semimajor axis is about 17.9 AU. According to Kepler's second law, and taking into account that the cometary perihelion is close to the Sun, this comet spends most of its time as far from the Sun as Neptune's orbit (figure 4).

Extension of Kepler's third law: mass determination

Kepler's third law offers the unique possibility to measure masses in the universe, when extended to binary systems. The constant which appears in this law is expressed as a function of the total mass $m_1 + m_2$ of both objects of the system and of the gravitational constant G (experimentally determined first by Henry Cavendish in 1798):

$$\frac{T^2}{a^3} = \frac{4\pi^2}{\mathcal{G}(m_1 + m_2)}.$$

The orbital period T and semimajor axis a can be derived by direct or indirect measurements. Therefore, their observation in a binary system may provide the measurement of the total mass of the system. Further indications, if available, are necessary to determine independently the individual masses m_1 and m_2.

As previously, with distances expressed in astronomical units, time in years, and mass M in solar mass units, the third law becomes (with $\mu = M/M_\odot$ and $M_\odot$ the mass of the Sun):

$$\frac{T^2}{a^3} = \frac{1}{\mu}.$$

As an example, the mass of the asteroid 45 Eugenia, surrounded by a small satellite discovered in 1998 at CFHT with ADAPTIVE OPTICS (figure 5) was derived from the orbital distance and period of this satellite, about respectively 1190 km (7.9×10^{-6} AU) and 4.7 days (0.0129 yr). This leads to a mass of about $3 \times 10^{-12} M_\odot$, or 6×10^{18} kg, for Eugenia.

Historical overview

Education

According to himself, Johannes Kepler was born on 27 December 1571 at 2:30 pm, after a pregnancy of 224

days, 9 h and 53 min, since he was conceived on 16 May at 4:37 am. This anecdote shows Kepler's close attachment to numbers. During his childhood in Weil (today in Baden-Württemberg, Germany) in a disunited family, he endured a very weak constitution, suffering from recurrent gastric problems, as well as from myopia and polyopia. His father became a mercenary and did not take care of his family; his mother narrowly missed being burnt at the stake. By chance, as he early proved himself to be a prodigious child, Kepler benefitted from the performance-based educational system founded by the Dukes of Württemberg. As Lutherians, they had promoted such a system in order to turn out the erudite clergy and the efficient administration they needed.

Johannes Kepler's education followed the classical steps: primary school, high school, seminary and finally university at Tübingen in 1589. There, he learned Greek, Hebrew, dialectics, ethics and physics. He met Michael Maestlin, who taught mathematics and converted Kepler to the Copernican system. As a young student, Kepler was already convinced about the mathematical superiority of the Copernican system compared with the Ptolemaic system. Maestlin derived from his observations of a comet in 1577 that only the Copernican system was able to define an adequate frame for the cometary orbit.

Kepler, who intended to pursue a position in religious life, was finally allowed in 1591 to devote his attention to theology. However, he did not obtain his doctorate directly, since he accepted in 1594 a position of *mathematicus* in Graz, Styria, where he started teaching the basic of astronomy. He acceded to the status of imperial mathematician in 1601, but went on practicing astrology his whole life long.

His first original work, *Mysterium Cosmographicum* (*The Sense of the Universe*), published in 1596, showed that, despite his encounter with the views of Copernicus, Kepler was bound by preconceived ideas derived from the Ptolemaic system. He considered the solar system as being governed by geometric relationships. He was convinced that all the objects moving in the sky had to be in harmony with divine secrets. Remarking that the known planets (from Mercury to Saturn, plus the Moon) were six (six being a perfect number since 6=1 + 2 + 3, namely the sum of all its divisors), he tried to find some trigonometrical relation between the distances of the planets to the Sun. Of course he failed. He also tried to organize the planetary orbits, ranged according to the heliocentric system, into the spheres inscribed in and circumscribed around the five regular polyhedra (figure 6). The agreement with observed data was quite acceptable.

Tycho Brahe's observations

In 1597, after a strong credit reduction following the death of the king, Tycho Brahe left his observatory in Denmark for Prague. Three years later, Kepler left his chair in Graz, because of the counter reformation and the persecution of Protestants. He accepted an invitation in Prague from Tycho Brahe and met him there. Their encounter proved to be very fruitful, despite tumultuous relationships because Brahe considered Kepler as an assistant instead of an equal. Tycho Brahe convinced Kepler to leave his numerological speculations. Kepler took Tycho's observations, made with very precise instruments but naked eyes, into the highest consideration. However, he did not try to follow Tycho's cosmological system with all planets orbiting the Sun but the Sun orbiting the Earth.

When Kepler started his collaboration with Tycho Brahe, he benefitted from the observations and theory of Tycho and of his disciple Longomontanus. Kepler was first supposed to work on the Moon's motion. However, he wished to work on the planetary eccentricities, and especially on Mars, since he was convinced, indeed rightly, that the orbit of Mars presented the strongest

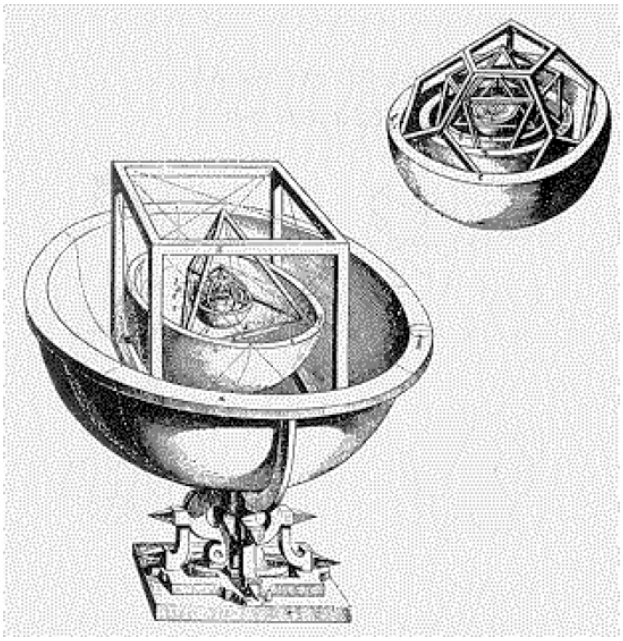

Figure 6. The five regular polyhedra and the planetary orbits. The orbit of the Earth is circumscribed by a perfect dodecahedron and a sphere containing the orbit of Mars, circumscribed by a tetrahedron and Jupiter's orbit, circumscribed by a cube and Saturn's orbit. Inscribing an icosahedron in the Earth's orbital sphere gives Venus's sphere, and then Mercury's sphere is inscribed in an octahedron.

eccentricity among the known planets—Mercury's eccentricity is actually greater, but the observations of this planet so close to the Sun cannot reach the same precision. Kepler found unacceptable the differences in longitudes and the complete disagreement in declinations between the best theoretical expectations and the observations. The differences reached more than 8 arcmin, compared with the 2 arcmin precision of Tycho's observations. Therefore, Kepler decided to abandon the Ptolemaic system and its derivatives, composed of series of epicycles. He then had to search for a new model.

Kepler's work

The fundamental novelty of his approach consists in the place devoted to the Sun. Contrary to Ptolemy, who considered the Earth as the unique point common to all planetary orbital planes, contrary to NICOLAUS COPERNICUS and to Tycho Brahe, who assigned this role, respectively, to the center of the Earth's orbit or to the center of the Sun's orbit, he calculated that the inclination of Mars' orbit was unambiguously defined when considering that the planetary orbital plane contains the Sun. He estimated this inclination to be about 1º50', comparable with the value accepted today: 1º51'. According to this observational conclusion, Kepler was reinforced in the relevance of the heliocentric system: he had in fact discovered that the Sun defined the best frame for a precise dynamical analysis.

He was aware, following the observations of Tycho Brahe, that the Earth does not move with a uniform speed, but slower or faster depending on the distance from the Sun. He recognized, and this constitutes the basis of his discovery, that the speed of the Earth at aphelion and perihelion is inversely proportional to the distance to the Sun at these points. He derived from these observations two false ideas that by chance cancelled—forces are inversely proportional to distances, but proportional to the velocity—and combined them in order to derive his second law. The second law was established first. Later, Kepler corrected his first form of the second law. He explained that not the velocity but its orthoradial component (perpendicular to the radius vector) is inversely proportional to the distance of the Sun.

In order to establish the shape of Mars' orbit, he made the assumption that the Earth orbit was circular, what is not too far from reality, despite his second law. The difference between the semimajor and semiminor axes of an ellipse is a second-order term of the eccentricity (figure 7). Nevertheless, it took him 8 yr to establish the laws, which became later Kepler's first and second laws. They were published in 1609 in the *Astronomia Nova* (*New Astronomy*). The third law, which finally needed another 9 yr of work, was published by Kepler in 1618, in *Harmonices Mundi* (*Harmony of the Universe*). In 1627, 3 yr before his death, he published the *Tabulae Rudolphinae*, in honor of his protector, which presented the planetary ephemeris based on his three laws.

A revolutionary approach

Why did the geocentric system, devised by Claudius Ptolemy, survive almost 1500 yr, since it required more than 70 simultaneous circular motions to derive the movements of the inner objects of the solar system? It gave an accurate description enough of what could be observed with the instruments at that time. It was able to predict the future paths of the planets well enough, according to the standards of those times. The planetary declinations were not predicted, but physical reasons could make explain this: the progressions of the planets, etymologically wandering objects, differ intrinsically from the stellar regularity by their annual parallax and complex motions in right ascension. Furthermore, this system completely agreed with the philosophical and cosmogonical doctrines prevailing at the time. Celestial motions had to be expressed in terms of combinations of circles, since the circle and uniform circular motion represented harmony. The careful analysis which puts the Sun at the center of the solar system and considers the Earth as one of the planets shows that orbital motion can be formulated within an adequate theoretical frame but needs to abandon the apparent evidence that the Earth holds a central position.

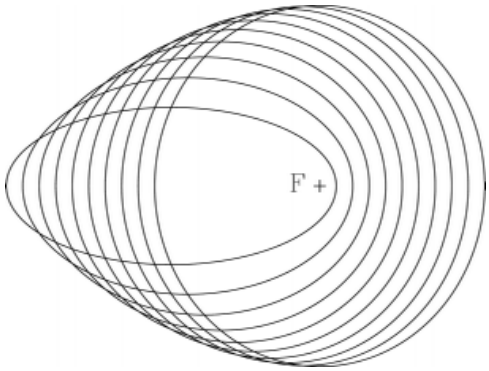

Figure 7. Set of ellipses with the same semimajor axis *a* but varying eccentricities *e* (0, 0.1, 0.2,…,0.9). Ellipses with small eccentricity remain nearly circular, but clearly decentered with respect to the focus F.

As described above, one cannot explain the role of Johannes Kepler in modern astronomy without reference to Nicolaus Copernicus and Tycho Brahe. Kepler was convinced of the superiority and perfection of the heliocentric theory, since that theory permitted in fact more harmony and simplicity than the previous view. He trusted in Tycho Brahe's observations, being of course impressed by the precision achieved, 10 times better than previously. Kepler actually had an original attitude towards observational results. He tried for a while to explain the agency of the planetary orbits with pure geometric methods. Since such theories failed to accurately fit observational data, he was to abandon this view and searched in other directions. When attempting to account for observed facts with new mathematical concepts, he succeeded, and then explored this way. Thus, Kepler admitted the ontological difference between the ideal figure—the circle—and its physical representation—the ellipse. The 9 yr separating the first two laws and the third one indicate that his new approach was not an easy way. Let us remember that physical notions such as instantaneous speed or differential calculus had not yet been invented.

Finally, Kepler's work can be considered as a cornerstone of physics and science during the 17th century. They were implicitly sustained by the following ingredients:

- observed facts prevail over *a priori* philosophical or theoretical schemes;
- the physical analysis needs to be conducted in an adequate reference frame;
- mathematical equations allow us to give physical laws in a condensed form.

These points must not induce the misinterpretation that Kepler's work was linearly developed, without error, delusion or fallacy. The greatest success of Kepler is due to his intense calculations: he was able to explore in detail numerous directions and to finally chose the best one. On the other hand, Kepler's laws remain purely kinematic: they describe the motion of planets but do not explain the cause of the movement. After Johannes Kepler, Galileo Galilei stated the essential concept of inertial frame, and Isaac Newton realized the synthesis of dynamics laws.

Beyond Kepler's laws

Implicit hypotheses

Through a modern physical approach, Kepler's laws are derived from the dynamics of a two-body system. The physics of such a system is based on the assumption that the two bodies are isolated and move under their mutual gravitational attraction. Thus, in the solar system, a given planet is supposed to only interact with the Sun, the perturbation due to the other planets being neglected. Kepler's laws also implicitly assume that the mass of the planet is negligible compared with the mass of the Sun. To a first approximation, this is true: the mass of the Sun represents 1000 masses of Jupiter. In fact, Newton's laws show that this second assumption can be relaxed. As soon as the two bodies remain isolated, their BARYCENTER furnishes a valid inertial frame. Then, instead of orbiting the Sun, the planet (the Sun as well) orbits the barycenter of the system.

Integrals

It is possible to express the content of Kepler's laws in very different ways. Let us examine the two-body interaction in terms of constant physical quantities.

- The two bodies being isolated, the total momentum of the system is constant. Then the frame based on the barycenter of the system is inertial.
- The force between the two bodies being central, and always directed towards the barycenter of the system, the angular momentum is constant. The plane of the trajectory contains the barycenter of the system and is perpendicular to the angular momentum.
- The gravitational interaction force deriving from a potential energy, the total mechanical energy of the system remains constant. The semimajor axis *a* depends only on the mechanical energy and not on the angular momentum.
- Another constant term comes from the fact that the force varies as the inverse of the square of the distance. The direction of the eccentricity vector indicates the direction of the pericenter (figure 8); its norm is the eccentricity *e*. Bound states have a negative energy and $e < 1$: they correspond to elliptical trajectories. Diffusion states have $e \geq 1$ and a positive energy.

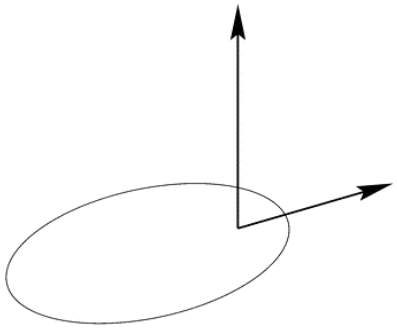

Figure 8. The trajectory plane and the direction of the major axis defined by the angular momentum and eccentricity vectors.

N-body interaction

What happens when the two-body interaction is not sufficient to account for reality? The recent case of the capture of comet Shoemaker–Levy 9 by Jupiter and the collision of the cometary fragments with Jupiter in July 1994 shows that the solar system is not only governed by the solar gravitational field. In a refined analysis, the perturbations due to the more massive bodies—especially the giant planets—are no longer negligible for long-term evolution, so that the two-body description, including only the central solar gravitational field, is invalid for an accurate description. The absence of any large object between Mars and Jupiter, the inclination of Uranus's rotation axis, the resonance between the motions of Neptune and Pluto (the ratio of their orbital periods is exactly 2:3) and the planetary rings, indicate that interactions between multiple objects (called *N*-body interaction) play a major role in the long-term evolution and stability of the solar system. New tools have been developed for such problems, such as Lagrangian mechanics. However, numerical computations are necessary to carry out the solutions of the *N*-BODY PROBLEM.

Kepler's Star

A supernova remnant in Ophiuchus, approximately 2.2° east of ξ Ophiuchi. The star was first seen in October 1604 by Johannes Kepler (1571–1630), and described in his book *De Stella Nova*. It reached a maximum apparent magnitude of -2.5 and remained visible to the unaided eye for about a year. The records indicate that it was a type Ia supernova. Today the visible remnants comprise just a few faint filaments and knotted fragments of nebulosity, but it is a strong source at radio wavelengths, with the identification 3C 358.

Khayyam [al-Khayyam], Omar [Abu ol-Fath ebn-Ebrahim ‘Omar ol-Khayyami of Nishapur] (c. 1044–c. 1123)

Poet, mathematician, astronomer, born in Nishapur, Persia (now Iran), to a family of Arabic tent makers (a translation of his name), an outstanding mathematician and astronomer. The Saljuq Sultan, Malikshah Jalal al-Din, appointed him to the observatory at Ray around 1074 to determine the solar calendar, as an aid to tax collection. Khayyam developed a calendar called *Al-Tarikh-al-Jalali*, which had an error of one day in 3770 years (superior to the Georgian calendar with an error of 1 day in 3330 years). It was based on Khayyam’s amazingly accurate determination of the length of the year as 365.242199 days. The length of the year is currently 365.242190 days, decreasing by about six units in the sixth decimal place over a century. Khayyam is best known as a result of Edward Fitzgerald’s translation in 1859 of nearly 600 short four-line poems, the *Rubaiyat of Omar Khayyam*, but versions of the verses in Persian literature pre-date Khayyam, and no-one knows which were written by him. The best known is the fateful quatrain:

> The Moving Finger writes; and, having writ,
> Moves on: nor all thy Piety nor Wit
> Shall lure it back to cancel half a Line,
> Nor all thy Tears wash out a Word of it.

Kiepenheuer-Institut für Sonnenphysik

The Kiepenheuer-Institut für Sonnenphysik (KIS) conducts experimental and theoretical investigations of physical processes on and within the Sun. Its headquarters are in Freiburg, Germany. The number of employees (scientific, technical and administrative) is about forty. The institute was founded in 1943 by Karl-Otto Kiepenheuer and, since 1978, it has borne the name of its founder. The KIS is a research institution of the State of Baden-Württemberg. The main observing facility of the KIS is the vacuum tower telescope within the OBSERVATORIO DEL TEIDE in Izaña on Tenerife, Spain.

For further information see http://www.kis.uni-freiburg.de.

Kinetic Theory of Gases

The theory, developed in the nineteenth century, notably by Rudolf Clausius (1822–88) and James Clerk Maxwell (1831–79), that the properties of a gas (temperature, pressure, etc) could be described in terms of the motions (and kinetic energy) of the molecules comprising the gases. The theory has wide implications in astrophysics. In particular, the perfect gas law, which relates the pressure, volume, temperature, and number of molecules in a gas, and which is fundamental to theoretical models of the interior of stars, is consistent with this theory.

Kirch family

Kirch, Gottfried (1639–1710)

Kirch, Maria Margarethe, née Winckelmann (1670–1720) his wife

Kirch, Christfried (1694–1740); and Kirch, Christine, his children

A family of astronomers and calendar-makers. Gottfried Kirch was born in Guben (Germany) and acquired a 4 foot quadrant and some telescopes, making observations of comets, including the comet of 1680, apparently the first comet to be discovered with a telescope. He discovered the star chi Cygni to be variable and observed Mira. He became director at the Berlin observatory in 1700 and began to prepare its calendars and ephemeredes. Christfried Kirch became director of the observatory himself in 1716. He observed star occultations, solar and lunar eclipses, Jupiter, Saturn and the comet of 1723. Maria (born in Panitsch, Germany) became interested in astronomy through Christoph Arnold of Sommerfeld, the so-called 'astronomical peasant', a self-taught astronomer. In 1692, she married Gottfried, working with him regularly, making observations and especially doing calculations. She discovered the comet of 1702. After Gottfried's death (1710), she continued to publish on her own, and when Christoph returned to Berlin, she worked with him too. Father, mother, son and daughter, Christine—the Kirch's published astronomical ephemeredes essentially as a family business.

Kircher, Athanasius (1602–80)

Polymath, born in Geisa a.d. Ulster, Germany, became a Jesuit. After a succession of academic appointments, he took up independent studies. He wrote an enormous range of books and sold exclusive rights to publish them for a large sum of money, so he was perhaps the first scientist who was able to live from the sale of his books. He corresponded with prominent astronomers such as GB RICCIOLI, GD CASSINI and HEVELIUS and acted as a kind of bulletin board for their observations. In one book Kircher describes a fantastic voyage through space to discuss his theories of the solar system. Accompanied by the 'music of the spheres', the two protagonists travel to other worlds, and converse with the intelligent life forms they find there. Kircher's philosophy was a blend of science and superstition combining empirical observation with magic and religion, foreshadowing popular science fantasy today.

Kirchhoff, Gustav Robert (1824–87)

Born in Königsberg, Prussia (now Kaliningrad, Russia), became professor of physics at Heidelberg where he collaborated with Bunsen, later professor in Berlin. With *Kirchhoff's laws of electricity* he extended the work of Ohm. He worked on black-body radiation and spectrum analysis. With *Kirchhoff's laws of radiation* he explained the dark lines in the Sun's spectrum as caused by absorption of particular wavelengths as light from a hot source passes through a cooler gas. He showed that a given element produced the same characteristic pattern of emission and absorption lines. This began the topic of stellar astrophysics, by which the composition, density, temperature and other physical conditions of a star's atmosphere can be found.

Kirkwood Gaps

Narrow regions in the asteroid belt where few or no asteroids are found. The gaps arise from orbital resonances with Jupiter: commensurabilities of the period of Jupiter with the period of an asteroid orbiting in a Kirkwood gap. Because of Jupiter's dominant gravitational influence, an object orbiting in one of these gaps would sooner or later be perturbed into a different orbit. For example, there is a pronounced gap at 3.28 AU, because an asteroid orbiting at this distance would have a period exactly half of Jupiter's. This orbit would be unstable, and the asteroid would soon be perturbed into a different one. This particular gap corresponds to a 2:1 commensurability and is often referred to as the 2:1 resonance; it marks the boundary between the Cybele group of asteroids and the outer edge of the main asteroid belt. Other gaps are found at other simple ratios of orbital periods, for example 3:1 and 5:2. However, at distances beyond about 3.5 AU the resonances correspond not to gaps but to groupings of asteroids: the Hilda group at the 3:2 resonance, for example.

A similar mechanism is responsible for shaping planetary ring systems. For example, the Cassini division in Saturn's rings corresponds to a 2:1 resonance with the orbit of the satellite Mimas, and ring particles at the outside of the A ring are in a 7:6 resonance with the co-orbital satellites Epimetheus and Janus. The connection between gaps and resonances was first pointed out in the mid-nineteenth century by Daniel Kirkwood.

Kirkwood, Daniel (1814–95)

Astronomer and mathematician, born in Harford, MD, became professor of mathematics at Delaware and at Indiana. He explained the structure of the distribution of asteroids in the asteroid belt as a result of the influence of Jupiter. If an asteroid resonates with Jupiter, i.e. has an orbital period that is a simple fraction (1/2, 2/3, ...) of the period of Jupiter, the repeated perturbation over time by Jupiter on the asteroid, when they have a close approach, ejects it into an eccentric, Earth-crossing orbit. The resulting lack of asteroids with these periods in the asteroid belt became known as *Kirkwood gaps*.

Kitt Peak National Observatory

Kitt Peak National Observatory (KPNO) is one of the cornerstones of the US system of publicly accessible astronomical facilities. Its two 4 m class telescopes are increasingly specialized towards wide-field applications that expand the discovery space for NASA missions and ground-based large-aperture telescopes. Time is awarded on the basis of scientific merit through a national system of peer review.

The US National Science Foundation established KPNO in 1958 under the leadership of the ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY. The site is the summit of a desert mountain at 2100 m, located 85 km kilometers southwest of Tucson, Arizona, on the land of the Tohono O'odham Nation. It was selected for clear skies, good seeing and a weather pattern allowing access to the North Galactic Cap.

KPNO offers time on three major telescopes: the Mayall 4 m; the modern 3.5 m WIYN telescope operated by the partnership of the Universities of Wisconsin, Indiana, Yale and the National Observatories; and the 2.1 m. Premier scientific instruments include an 8000 pixel-square CCD Mosaic imager at the 4 m prime focus, a bench spectrograph coupled to the 1 degree focal surface by 100 optical fibers at the WIYN, and a simultaneous four-color near-infrared imager at the 2.1 m.

KPNO also acts as the site host for a number of major facilities, including telescopes of the NATIONAL SOLAR OBSERVATORY, the NATIONAL RADIO ASTRONOMY OBSERVATORY, the University of Arizona and eight university-based consortia.

Kleinmann–Low Nebula (KL Nebula)

An extended, dusty region of star formation behind the Orion Nebula, position RA $05^{h}\ 35.2^{m}$, dec. $-05^{\circ}\ 22'$, discovered in 1967 by Douglas Kleinmann and Frank Low. There are several discrete sources of infrared radiation, including the Becklin–Neugebauer object, thought to be young stars or protostars.

Konkoly Observatory

Konkoly Observatory in Budapest is equipped with a 1 m Ritchey–Chrétien–Coudé telescope, carrying out observational astronomical studies, mainly related to the physics of the variable stars, galactic structure, solar activity and the terrestrial upper atmosphere. These tasks imply operation of the internationally recognized observational network developed during the last three decades. A very important task—perhaps the most important one—is the development of the national astronomical information system, including the observatory's library.

The main areas of work include studies concerning the behavior of variable stars: investigation of multiple periodicity and period changes of pulsating variables, as well as research on stellar activity of various time-scales. Studies related to the galactic structure and physics of interstellar matter with an emphasis on the star-forming processes. Studies of the upper atmosphere of the Earth and Mars with space-borne equipment. Studies on solar activity, investigation of the problems of the problems of sunspots and prominences.

Korolyov [Koroljow], Sergej [Sergey, Sergei] Pavlovich [Pawlowitsch] (1907–66)

Rocket designer, founder of the Soviet space program, born in Zhitomir, Russia. After pioneering experiments on rockets in Moscow, Korolyov fell foul of Stalin's pogroms but was recalled from the stalags to make liquid-fuel rocket boosters for military aircraft. After the war he took over captured German V-2 missiles, and developed the Soviet Union's first intercontinental ballistic missile. He directed the design, testing, construction and launching of the Vostok, Voskhod and Soyuz manned spacecraft as well as of the unmanned spacecraft in the Cosmos, Molniya and Zond series. His identity and his key work for Russia's space program, as a Soviet analog to the USA's VON BRAUN, were not known in the West until his death.

Kraus, John (1910–)

Radioastronomer, born in Ann Arbor, MI, became professor of electrical engineering and astronomy at Ohio State University, and director of the Ohio State–Ohio Wesleyan Radio Observatory. Author of widely used textbooks on radio techniques, he is the inventor of many types of radio antennas. Surveyed the radio sky at centimeter wavelengths, mapped and cataloged some 20 000 radio sources, including many quasars. Instigator of an extensive search for extraterrestrial artificial radio signals. The search serendipitously discovered natural narrow-band signals, interpreted as cold, isolated neutral hydrogen clouds, and in 1977 found the 'WOW!' signal (annotation by Jerry Ehman on the computer print-out) that, being celestial, narrow-band and intermittent, suggested an intelligent origin. However, the signal never recurred from that direction and is now attributed to a signal from a secret Earth-launched space probe, rather than a star.

Kroto, Sir Harold (1939–)

Spectroscopist, born 'Krotoschiner' in Wisbech, Cambridgeshire. Nobel prizewinner for chemistry (1996) with chemists Robert F Curl and Richard E Smalley 'for their discovery of fullerenes'. Became professor at the University of Sussex. Worked on microwave spectroscopy, measuring and calculating the spectra of small molecules. Although many such molecules do not exist naturally on Earth, they exist in space and can be detected by radioastronomy, both in stellar atmospheres and in interstellar gas clouds. Kroto was particularly interested in carbon-rich giant stars and had identified spectral lines in their atmospheres as long-chained molecules of carbon and nitrogen, termed cyanopolyynes. To study their formation, he allied with physical chemists Smalley and Curl and they reproduced conditions in stellar atmospheres in laboratory equipment. Studying the chain of events that might produce cyanopolyynes, they discovered carbon in clusters of 60 atoms arranged in a soccer ball-like structure called buckminsterfullerene, after the American architect R Buckminster Fuller, inventor of the geodesic dome. Like graphite and diamond, C-60 fullerene is expected to be a constituent of interstellar space, where it will become hydrogenated by attached hydrogen atoms.

Kuhn, Thomas S (1922–96)

Science historian, born in Cincinnati, OH. Developed a theory of scientific revolution which visualized science not as a steady progression of knowledge, but as 'a series of peaceful interludes punctuated by intellectually violent revolutions' in which one world view is suddenly replaced by another. For example, EINSTEIN's theory of relativity overthrew Newton's concepts of physics, and GALILEO's legendary experiments banished the Aristotelian theory that bodies fell at a speed proportional to their weight. But scientists were not typically objective, free thinkers, Kahn claimed. They accepted and usually related their work to a paradigm, an archetypal solution to a problem. Thus, astronomers resisted, for a long time, research that challenged the paradigm of Ptolemy's theory that the Sun revolves around the Earth, setting aside, for example, the work of ARISTARCHUS, who suggested as long ago as the third century BC that the planets revolve around the Sun. It took nearly 2000 years before the Ptolemaic paradigm was suddenly replaced by the new paradigm of the scientific revolutionary, COPERNICUS.

Kuiper Belt

The trans-Neptunian solar system is now known to contain a vast population of icy bodies called the Kuiper Belt, first discovered by David Jewitt and Jane Luu in August of 1992. The discovery confirmed that the region immediately beyond the planets is not merely empty space but is instead richly populated with a vast reservoir of fossil remnants from the original solar nebula. The enormous scientific potential of the Kuiper Belt was soon recognized and the belt is now the subject of intensive observational and dynamical studies.

The interest in the Kuiper Belt originated with the problem of the origin of the short-period COMETS (comets with orbital periods shorter than 200 yr). Jan OORT proved in 1950 that the long-period comets (those comets with orbital periods longer than 200 yr) come from the OORT CLOUD, a spherical cloud with radius on the order of 10 000 AU. It was thus simply assumed that the short-period comets were somehow derived from the long-period comet population, perhaps through capture by the giant planets, primarily Jupiter.

This assumption was cast in doubt in the 1970s, when Paul Joss pointed out that the probability of capture of the long-period comets by Jupiter was too small to explain the observed number of short-period comets. Because of the limited computer power at the time, Joss' result went largely unconfirmed until 1988, when the Canadian astronomers Martin Duncan, Tom Quinn and Scott Tremaine carried out computer simulations of the capture process of the long-period comets by the giant planets. They confirmed Joss' result, but also found that, during capture, the orbital inclination distribution was roughly preserved. This means that, if the original population contained comets with high inclinations, the captured population should also contain comets with high inclinations. This result agrees very well with observations of the long-period comets: the Oort cloud is a spherical cloud, implying that the long-period comet inclinations should also be roughly spherical, which is indeed the case. However, the short-period comets mostly have low-inclination orbits, inclined less than 30° from the ecliptic plane. The simulations' results thus imply that a spherical cloud like the Oort cloud could not produce a flat structure like the short-period comets; instead, a much better source would be a flat belt of comets in the outer solar system. This comet belt is now called the Kuiper Belt, after the Dutch astronomer Gerard KUIPER.

This idea of a trans-Neptunian comet belt was actually first mentioned in 1949 by an Irishman named Kenneth EDGEWORTH, then elaborated upon by Gerard Kuiper in 1951. Their basic argument was that there was no *a priori* reason why the solar system should end abruptly at Neptune or Pluto. Perhaps large planets could not form beyond Neptune, but smaller bodies might be able to. Edgeworth and Kuiper thus envisioned a population consisting of residual 'PLANETESIMALS' (small solid bodies) left over from the formation of the planetary system. Also, because of the low temperatures, it seemed likely that these distant objects would be ice rich, identical to comets.

In 1987, shortly before Duncan, Quinn and Tremaine published their results, spurred on by the dramatic contrast between the apparent emptiness of the outer solar system and the richly populated inner solar system (remember that Pluto was the only permanent solar system object known beyond Neptune at the time), Jewitt and Luu started a telescopic survey in order to address the question of the contents of the outer solar system. After five years of searching, they detected the first Kuiper Belt object (KBO), 1992 QB1, in August 1992. The Kuiper Belt has become the new frontier of the solar system.

In 2002, astronomers determined that 2002 LM60, an icy Kuiper belt object dubbed Quaoar, by its discoverers, is the largest body found in the solar system since the discovery of Pluto 72 years ago. Quaoar (pronounced kwa-whar) is about half the size of Pluto. Like Pluto, Quaoar dwells in the Kuiper belt. It is the farthest object in the solar system ever to be resolved by a telescope. Quaoar is about 4 billion miles away from Earth, well over a billion miles farther away than Pluto. Unlike Pluto, its orbit around the Sun is circular, even more so than most of the planetary-class bodies in the solar system. Although smaller than Pluto, Quaoar is greater in volume than all the asteroids combined (though probably only one-third the mass of the asteroid belt, because it is icy rather than rocky). Quaoar's composition is thought to be largely ices mixed with rock, not unlike the

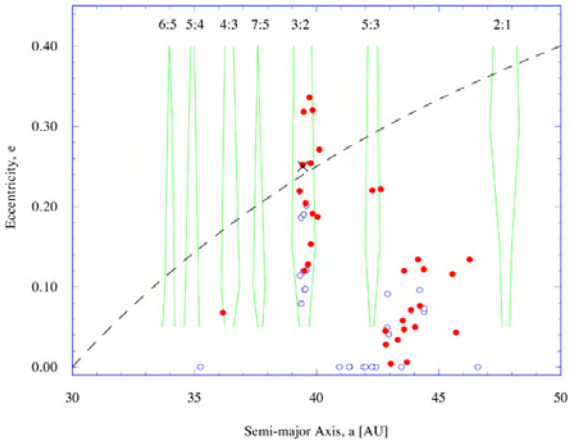

Figure 1. Semimajor axis versus eccentricity for KBOs. Solid circles denote objects observed over at least 2 yr (secure orbits), empty circles objects observed only once (probably lost). Pluto is marked by X. Neptune is at $a = 30$ AU. The dashed curve marks a perihelion distance of 30 AU; objects above the line are Neptune crossers (i.e. orbits are unstable). Orbital elements computed by Brian Marsden.

makeup of a comet, though 100 million times greater in volume.

Structure of the Kuiper Belt

Neptune defines the inner edge of the Kuiper Belt. While the outer edge of the belt remains unknown, it is known that the belt extends at least as far as ~130 AU (see the section on scattered KBOs). Researchers have counted 346 KBOs since they were first recognized in the early 1990s, but, assuming a 4% albedo for the ones known, it is estimated that there are at least 70 000 of them with diameters larger than 60 mi (100 km). The known KBOs are sufficient to give us a general idea of the radial distribution of the belt, which is plotted in figure 1. It can be seen that the radial distribution of the belt is highly non-uniform. The region from Neptune to ~42 AU is empty owing to perturbations by the planet, except for a concentration of objects at 39 AU, the location of the 3:2 mean motion resonance of Neptune. Based on their dynamics, the known KBOs can be divided roughly into three distinct categories: the classical KBOs, the resonance KBOs and the scattered KBOs.

Classical KBOs

The classical KBOs are characterized by low-eccentricity, low-inclination orbits, suggesting that they formed directly from the solar nebula and have managed to preserve their primordial orbits.

Resonance KBOs

The Kuiper Belt contains a number of 'mean motion resonances' with Neptune, regions where periodic perturbations by the planet have induced special dynamical properties restricted to the regions. An object in an m:n resonance would make n orbits around the Sun for every m orbits completed by the planet. For example, Pluto is in the 3:2 resonance (located at 39 AU), meaning that it completes 2 orbits for every 3 orbits completed by Neptune. Renu Malhotra showed that some of these resonances are stable, which should lead to population enhancement inside the resonances, even if their immediate environs are unstable owing to Neptunian perturbations. However, the only resonance currently known to be densely populated is the 3:2 mean motion resonance. Just as the resonance protects Pluto from close encounters with Neptune, it also protects other members of the resonance (now called 'PLUTINOS' to highlight their dynamical similarity with Pluto). In view of the abundance of the Plutinos, Pluto is then best understood as the largest known KBO, rather than as a deviant planet. (It should be noted that Pluto may not be the only large body that formed in the Kuiper Belt: because of its strong similarities with Pluto, it is suspected that the Neptune satellite TRITON also originated in the Belt but has somehow been captured into an orbit around Neptune.) The apparent fraction of Plutinos among the known KBOs is roughly 35%, but this is an overestimate owing to several observational biases (including the fact that the resonance lies near the inner edge of the Kuiper Belt, rendering Plutinos easier to detect). The bias-corrected Plutino fraction is in fact closer to 10–20%, and the number of Plutinos larger than 100 km is ~30 000. The discovery of the Plutinos was completely unexpected, unpredicted by any theory.

Given that objects inside 42 AU are quickly ejected by Neptune, the question is as to how the 3:2 resonance became populated. Malhotra proposed that the resonance became populated during the radial migration of the giant planets. It has long been known that, during the final stages of planet formation, the giant planets grew large enough to scatter away nearby planetesimals. During the scattering process the planets exchanged angular momentum with the planetesimals, but, because of their different masses, the exchange is different for each planet. The net effect was that Jupiter lost angular momentum and its orbit shrank, while the orbits of the other giant planets expanded outward. Neptune may have migrated as much as 5 AU outward from its original location. As Neptune moved outwards, its mean motion resonances also moved with it, sweeping through the planetesimal disk. Along its path the 3:2 resonance could have captured PLUTO–CHARON, along with the Plutinos. The resonance capture theory also predicts clear population enhancements at other resonances with a strong capture probability, such as the 2:1 resonance at 48 AU. No 2:1 resonance KBO has been identified at this time but this may be due to the fact that the 2:1 resonance is significantly further away than the 3:2 resonance and its members would be much more difficult to detect. Malhotra pointed out that how many planetesimals these resonances succeeded in capturing depended on the migration rate of Neptune. A measurement of the relative resonance populations could thus provide an unanticipated method to calculate the migration rate of Neptune. This is a scientific question previously thought to be out of the realm of direct observations.

Scattered KBOs

The third dynamical class in the Kuiper Belt, the scattered KBOs, possesses large, eccentric orbits and is exemplified by the object 1996 TL_{66} (figure 2). Whereas the known classical KBOs are clustered inside 50 AU, with an eccentricity $e = 0.59$, and a semimajor axis $a = 85$ AU, 1996 TL_{66} reaches as far as 130 AU at aphelion. It is the only scattered KBO known thus far, but is most likely just the first detected of a much larger population of similar bodies. The scattered KBO population is estimated to contain ~10 000 objects like 1996 TL_{66}, with a total mass of ~0.05 M_{Earth} contained between ~40 and 200 AU (1 $M_{\mathrm{Earth}}=6\times10^{24}$ kg is the mass of the Earth). Although this estimate is crude, there is little doubt that the Kuiper Belt extends much further than suspected.

The origin of the scattered Kuiper Belt is unknown. One hypothesis posits that it is a natural product of the scattering process that produced the Oort cloud. The Oort cloud is believed to consist of planetesimals scattered by

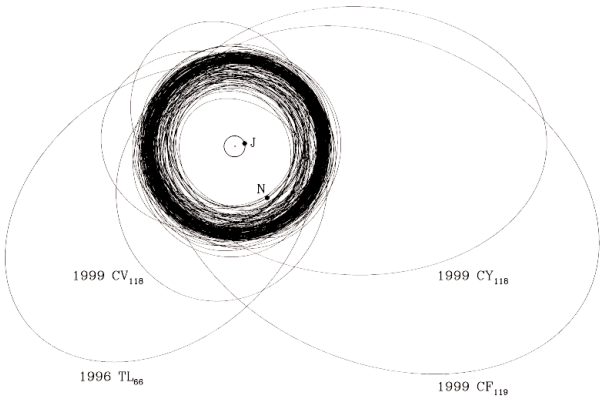

Figure 2. Planar view of the outer solar system. The dense band of orbits refers to the best observed KBOs (including Pluto), while the large, eccentric orbits of 1996 TL_{66}, 1999 CV_{118}, 1999 CY_{118} and 1999 CF_{119} extend far beyond the previously known Kuiper Belt, and identify them as scattered KBOs.

the giant planets (primarily Uranus and Neptune) when they nearly reached their full sizes. It is easy to imagine that perhaps not all the scattered planetesimals reached Oort cloud distances. Some perhaps were scattered to more intermediate distances, perhaps forming a radial distribution of material that bridges the gap from the planetary region to the Oort cloud. This scenario predicts that the outer solar system would be continuously populated, with the classical Kuiper Belt just beyond the planets, followed by the scattered Kuiper Belt which would extend all the way to the Oort cloud.

Population statistics

Thanks to ground-based surveys, the census of KBOs in the hundred kilometer range is now well established. The luminosity function of the Belt (inside the 30–50 AU region) can be obtained from the cumulative surface density measured by recent ground-based surveys. Fitting the surface density with the power law

$$\log[S(m_R)] = \alpha(m_R - m_0)$$

where m_0 is the (red) magnitude at which the surface density S reaches $1^{\circ-2}$, and 10α gives the slope of the luminosity function. Fitting the ground-based data yields α=0.58±0.05 and m_0=23.27±0.11. In other words, there is 1 KBO$^{\circ-2}$ at red magnitude m_R=23.3, increasing by ~4 per magnitude. The luminosity function outside $20<m_R<25$ may be different, and remains to be assessed.

The luminosity function provides a clue as to the size distribution in the Kuiper Belt, i.e. how the population is divided into different size ranges. Assuming that KBOs obey a differential power law size distribution of the form $n(r)\,dr : r^{-q}\,dr$, where $n(r)\,dr$ is the number of objects in the radius range from r to $\mathbb{r}+\,dr$, the ground-based observations are best fitted with $q = 4$. HUBBLE SPACE TELESCOPE observations suggest a larger q, but this result remains controversial.

Given the size distribution, it is possible to calculate the total mass provided that the minimum and maximum radii of the distribution are also known. This is not the case for the Kuiper Belt, and an exact determination of the belt's total mass has not been possible. The current assessment of the Kuiper Belt population can be summarized as follows. The total mass between 30 AU and 50 AU is estimated at ~$0.2M_{\rm Earth}$. There are no observations of the Kuiper Belt at larger distances, but the mass of the belt at larger distances has been roughly constrained by the dynamics of spacecraft and comets. If a massive belt existed at great distances, it would have affected the motion of spacecraft such as Pioneer 10 (currently at 67 AU), VOYAGER 1 (65 AU) and Voyager 2 (51 AU) as well as the motion of comet Halley. The estimated upper limit is $5M_{\rm Earth}$ within 100 AU—well above the mass estimated from observations of the scattered Kuiper Belt (see section on scattered KBOs).

This $0.2M_{\rm Earth}$ mass inside 50 AU includes ~70 000 objects larger than 100 km (in comparison, the asteroid belt contains ~230 asteroids larger than 100 km). Objects with radius <50 km are numerous but lie beyond the detection capabilities of most ground-based telescopes, while very large bodies (radius >250 km), although easily detectable from the ground, are rare. Note that the known KBOs are much larger than the known short-period comets (typical radius: 5–10 km), implying that the former cannot be the direct precursors of the latter. It has been postulated that the short-period comets were actually collision fragments that were then ejected from the Belt.

However, we must bear in mind that the Kuiper Belt has been much eroded dynamically since its formation, and the current population is but a remnant of the original population. From models that simulate the growth of KBOs, it is estimated that an original mass of ~10 $M_{\rm Earth}$ is needed to create the observed Kuiper Belt population.

Short-period comets and Centaurs

It is believed that the short-period comets originated in the Kuiper Belt, although it is not clear which part of the belt (the classical or scattered Kuiper Belt) is the main source. If comets originated as classical KBOs, these KBOs could have escaped from the belt in a slow 'leakage' via close encounters with Neptune. The KBOs would maintain their stable orbits inside the Kuiper Belt for 3–4 billion years before suffering a close encounter with Neptune. Once a Kuiper Belt object encounters Neptune, it has a 33% chance of being scattered into a short-period comet orbit. Other (less likely) alternative fates include being ejected from the solar system or colliding with the planets.

The timescale to go from a Kuiper Belt orbit to an inner solar system orbit is about 10^7 yr. Thus, if the Kuiper Belt is continuously supplying short-period comets, one would expect to see ex-KBOs making their way into the inner solar system. The prime candidates for these ex-KBOs are the 'CENTAURS', objects whose

Copyright © Nature Publishing Group 2003

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

orbits cross those of the giant planets. The Centaurs' orbits are highly chaotic and it is apparent that their residence between the giant planets is only temporary. The transient nature of the Centaurs, and their location between the Kuiper Belt and the inner solar system, renders them the best candidates for recent Kuiper Belt escapees that are perhaps now evolving into short-period comets. Seven Centaurs are known at the present time. Interestingly, the brightest Centaur, 2060 CHIRON, has been proven to be a comet, so there is no doubt that Centaurs are ice-rich bodies that can sublimate under the right conditions. The Centaurs are important because (1) they provide the missing dynamical link between the KBOs and the short-period comets and (2) they are much closer (brighter) than the typical KBOs, and therefore make much better targets for physical studies.

Physical properties of KBOs

The properties of KBOs are of intense interest since these bodies have changed relatively little since their time of formation in the solar nebula. Laboratory experiments predict that KBOs should have an 'irradiation mantle' produced by high-energy particle irradiation of surface ices. When carbon-containing ices (e.g. CH_4 or CO) are irradiated by the high-energy particles prevalent in interplanetary space such as cosmic rays and solar wind particles, this irradiation leads to the selective loss of hydrogen in surface materials, while encouraging the formation of carbon bonds. The irradiation thus alters the surface chemically and physically. Exactly how the color and reflectivity of the irradiated ice change with time depends on the specific composition and the irradiation flux. For example, cosmic rays are very energetic (10 MeV-10 GeV range) and can penetrate several meters, whereas solar wind particles (<1 keV) can only penetrate depths ~1 μm. The result is a dark, non-volatile solid residue that is rich in carbon compounds. After 4.5 billion years, KBOs and Centaurs are thus expected to sport a thick non-volatile, organic-rich crust, dark owing to its high carbon abundance. Note that this non-volatile crust would have a composition quite different from the interior, which is still pristine ice. The thick crust may survive on the object's first entry into the inner solar system.

Ideally, optical and infrared spectra are needed in order to assess the surface composition of KBOs and confirm or refute the irradiation mantle hypothesis. Unfortunately, physical properties of KBOs are extremely difficult to obtain because of their faintness. Until recently, instead of spectra, astrononomers have had to rely on optical and near-infrared broadband colors for compositional information. Surprisingly, KBOs and Centaurs exhibit a wide range of optical colors, ranging from nearly neutral (i.e. all wavelengths are reflected equally) to very red (red wavelengths are preferentially reflected), which is unmatched by known comets and asteroids. In fact, KBOs and Centaurs possess the most extreme red colors seen among small solar system bodies. The large spread of colors suggests considerable diversity in the materials present on the surfaces of KBOs. Interestingly, the very red optical spectrum of the Centaur 5145 Pholus has been reproduced with irradiated ices containing a mixture of N_2 and CH_4. The unique red colors suggest the presence of an indigenous surface material not seen closer to the Sun and are consistent with the irradiation mantle.

The irradiation hypothesis predicts that irradiation mantles should exist on the surfaces of all KBOs, thus resulting in similar colors for all KBOs. The observations clearly indicate otherwise. Astronomers have not conclusively identified the cause of the color diversity, but two simple explanations have been suggested for the origin of the color diversity. One possible explanation is that KBOs possess intrinsically different compositions, and that the different colors are tracers of the compositional variations. This has been observed in the asteroid belt, where asteroids show different compositions that seem to be related to their sites and temperatures of formation. However, the KBOs, as far as we know, all formed more or less where they are now seen, implying formation temperatures in the range 40–50 K. It is hard to see how strong compositional differences might arise if there is little change in the formation temperature, but they might occur, and this is a possible interpretation of the data. Another possible explanation is that collisions in the Kuiper Belt might puncture the irradiation mantles on some objects, revealing fresh interior material, as well as showering nearby regions with impact debris. The freshly exposed crater and the impact debris would be unirradiated material, and thus should be of a different composition and less red than the irradiated mantle. The overall color of a particular KBO would then depend on how much of the surface area is covered by recently excavated craters. This is analogous to the resurfacing of the Moon, where recent impacts have deposited bright rays on the darker background material. This collision resurfacing hypothesis predicts albedo variations on the surface of KBOs, and a test of this prediction may soon be feasible with the largest telescopes.

Besides this preliminary result on the surface composition, little information is available about other properties of KBOs. Attempts to measure their shapes and rotation periods have so far yielded inconclusive results.

Origin of the Kuiper Belt

From the apparent connection of the Kuiper Belt with so many solar system objects, it is clear that the belt played an important role in shaping the outer solar system. However, how did the belt form, and why did planetary accretion take the form of a large population of small bodies instead of a single large planet? The near-circular, low-inclination orbits of KBOs suggest *in situ* formation from the solar disk—this hypothesis has indeed been supported by dynamical simulations. Integrations of orbits beyond Neptune by Matt Holman, Jack Wisdom, Martin Duncan and Hal Levison showed that a belt of trans-Neptunian bodies formed at the beginning of the

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

solar system would survive for the age of the solar system. The implication is that the Kuiper Belt is simply a remnant fossil from the solar nebula that was left behind because it was not scattered away or incorporated into planets. All other solar system bodies (e.g. planets, asteroids, known comets) have been heavily modified by solar heating or collisions over the age of the solar system. Stranded far beyond the planets, little has happened to KBOs since birth. Although their top surface layers have been modified by irradiation and collisions, in this case collisions are actually beneficial to astronomers in that they reveal the pristine interior ice. In other words, in the Kuiper Belt is the solar nebula 4.5 billion years on, and with its discovery astronomers now have the chance to make direct observations of the nebula itself. This is the main scientific appeal of the Kuiper Belt.

Comparison with circumstellar disks

Are circumstellar disks extrasolar Kuiper Belts?

The recognition of our own Kuiper Belt leads us naturally to suspect that similar planetesimal structures might exist around other stars. It is now well known that dust disks are common around main-sequence stars, the most famous of which is the dust disk surrounding β Pic, suspected to be a young planetary system. Dust in disks like β Pic's is depleted by several destruction mechanisms such as radiation pressure, POYNTING–ROBERTSON drag and collisional destruction. If the dust is to be in steady state, it must be continuously replenished by some as yet unknown source. A simple and plausible source is collisional grinding between planetesimals in a Kuiper Belt.

The discovery of the Kuiper Belt proves that, indeed, planetary accretion at large distances is more likely to take the form of numerous small bodies rather than a single large planet. Recent discoveries of extrasolar planets suggest that planetary accretion is not an uncommon phenomenon, further amplifying our interest in extrasolar planetary systems. The obvious question then is whether we are observing an extrasolar Kuiper Belt in β Pic. Put in another way, does the Kuiper Belt also include a dust disk?

Kuiper Belt dust production rate

KBOs in the 100 km diameter range are relatively rare in the belt and are not likely to collide with each other. However, these large bodies are likely to collide with the much more numerous small bodies, e.g. those in the 1 km radius range. If we extrapolate the current KBO census down to 1 km radius range, there would be ~10^9–10^{10} of these small bodies. A crude estimate of the dust production rate through collisional grinding of these small projectiles would be 400–4000 kg s^{-1}.

This dust would be subjected to several destruction mechanisms. Grains with radius between 0.05 and 0.5 μm would be blown out of the solar system by radiation pressure very quickly. Larger grains would spiral toward the Sun under the effect of the Poynting-Robertson force and solar wind drag on the timescale of a few ×10^7 yr (some 20% of this dust should reach the orbit of the Earth, but would be difficult to distinguish from asteroidal dust). Finally, dust grains may also be destroyed by collisions with interstellar grains, or with other particles in the belt. Taking these destruction mechanisms into account, it would take on the order of 10^6 years to deplete the dust in the Kuiper Belt.

The non-detection of Kuiper Belt dust by the infrared satellite COBE placed an upper limit of $0.3M_{\rm Earth}$ on the amount of dust present in the Kuiper Belt. More stringent constraints for the amount of dust in the Kuiper Belt come from spacecraft that have traveled through the Kuiper Belt itself, such as Voyager 1 and 2 and PIONEER 10 (see the section on population statistics). Voyager 1 traveled north from the ecliptic, reaching an ecliptic latitude of +35°, while its twin Voyager 2 traveled southward and reached an ecliptic latitude of –34°. Both spacecraft detected numerous dust impacts that could only come from dust in the Kuiper Belt. Assuming that the Kuiper Belt is roughly 30° thick, and assuming an average dust grain size of 1 μm in radius, the Voyager results imply that there is at present ~$10^{-8}M_{\rm Earth}$ of dust in the Kuiper Belt. It is unlikely that such a small dust mass can be detected in the near future from any ground-based or near-Earth telescope. Another mass limit was obtained from Pioneer 10, which has spent more than a decade in the Kuiper Belt. Based on the fact that no dust impact damaged the spacecraft's propellant tank, scientists estimated that the Kuiper Belt could not contain more than $0.1M_{\rm Earth}$ in centimeter-size dust particles.

The dust mass in the β Pic disk is very uncertain but, roughly, the amount of dust in β Pic contained in micron-size particles is ~$3\times10^{-3}M_{\rm Earth}$, or 10 000 times more dust than is currently contained in our Kuiper Belt. However, as was pointed out earlier, if the original Kuiper Belt population is ~100 times larger than the current population, the dust content (which scales as the square of the number of bodies) must have been ~10 000 times larger. This suggests that the early Kuiper Belt (at the age of 100 million years or so) may have been much like the β Pic disk. Other indirect evidences exist which point toward this scenario. Recent HST images of the main sequence stars HD 141569 and HR 4796A clearly show the existence of dust rings (see URL http://oposite.stsci.edu/pubinfo/pr/1999/03/pr-photos.html). In particular, HR 4796A is surrounded by a ring 70 AU in radius, whose morphology is highly reminiscent of our Kuiper Belt. These observational and theoretical results support the hypothesis that many of the known disk systems can be identified with the Kuiper Belt, i.e., the Kuiper Belt is most likely a common phenomenon in stellar systems.

The future of the Kuiper Belt

What we have learned thus far about the Kuiper and its implications for the early solar system is only the tip of the iceberg. Although surveys have continuously identified new KBOs since 1992, studying KBOs is quite a different story from finding them. Until recently, there

Copyright © Nature Publishing Group 2003

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

was little astronomers could do besides trying to increase the sample of known KBOs. However, the imminent arrival of a new generation of large (8 m–10 m class) telescopes promises to galvanize the field by giving astronomers the capability to study these faint objects in detail. Kuiper Belt research is also given a great boost by new and on-going large sky surveys whose purpose is to find large, bright KBOs (red apparent magnitude m_R<22) suitable for detailed physical studies. For example, recent optical and near-infrared spectroscopic observations of the scattered KBO 1996 TL_{66} (the brightest KBO after Pluto and Charon) revealed a surface that is neutral in color and shows no sign of abundant ices as seen on Pluto. This rules out the possibility of a pure water ice surface on TL_{66}, although small amounts of other ices (including dirty water ice) cannot be ruled out. Obviously spectroscopic observations of many more KBOs are needed before astronomers can claim to understand the composition of the Kuiper Belt, but this goal is now in sight.

To properly interpret the spectroscopic observations in terms of the molecules and grains that make up the KBO surfaces, astronomers will also have to rely on laboratory experiments that simulate (as best as technology allows) the environment of the Kuiper Belt. For example, the experiments should simulate the irradiation and photoprocessing of a wide variety of ices by ultraviolet photons. Similar experiments have been performed in the past, but the focus in the past had been on INTERSTELLAR GRAINS, whose source of irradiation is mainly high-energy cosmic ray particles. Such experiments will have to be modified to approximate the Kuiper Belt environment. The results can then be compared with the extensive body of knowledge on interstellar grains, giving astronomers the unprecedented opportunity to observe the evolution of interstellar material as it is incorporated into a solar nebula. In short, Kuiper Belt research is in its nascent stage and its demands will push astronomical technology to the limit, but the potential reward is the answer to a question that has driven astronomers since the days of Copernicus: how the solar system formed (see also ORIGIN OF THE SOLAR SYSTEM).

Kuiper, Gerard Peter (1905–73)

First applicant of multidisciplinary techniques to the study of the solar system, i.e. the first planetary scientist, born in Harencarspel, Netherlands, educated at Leiden, and moved to the USA, becoming director of Yerkes Observatory and founding (1960) and directing the Lunar and Planetary Laboratory of the University of Arizona. Spectroscopically detected the methane atmosphere on Saturn's satellite Titan and the carbon dioxide atmosphere of Mars. Discovered Miranda (fifth moon of Uranus), and Nereid (second moon of Neptune). Identified the belt of comet-like debris at edge of solar system (*Kuiper's belt*; *see also* KENNETH EDGEWORTH). Selected the landing sites on the Moon for the Ranger probes and Apollo landings. The *Kuiper Airborne Observatory* for infrared astronomy (used extensively for remote sensing of the planets) was named for him.

Kuo Shou-Ching (1231–1316)

Chinese astronomer, constructed at Linfen (Shansi) the 'Simplified Instrument', a torquetum to observe the positions of the stars. It was so-called because it was equatorially mounted, and was thus able to omit some rotations and calculations which followed from the original Arab design, altazimuthally mounted. The instrument survives at Purple Mountain Observatory, having been moved to Nanjing in the Ming dynasty, when it had been forgotten that the change in latitude rendered it useless. According to JOSEPH NEEDHAM, the idea of this instrument was transmitted back through Arabic astronomy, via Gemma Frisius to Tycho Brahe, and influenced his instruments and concept of equatorial astronomy. Shou-Ching developed spherical trigonometry, as well as making a clockwork-driven celestial globe.

Lépaute, Nicole-Reine Etable, née de la Briére (1723–88)

French astronomer, aide to JOSEPH LALANDE calculating circumstances of an annular eclipse of the Sun visible in France and Europe. She worked on the predictions for the return of HALLEY's Comet in 1759, including the perturbations by Jupiter and Saturn. She also assisted her husband, the royal clockmaker of France, making calculations such as the number of oscillations per unit time of pendulums of various lengths.

La Condamine, Charles Marie de (1701–74)

Born in Paris, France, had an army career, was sent by the Académie Royale to Peru to measure the length of a degree of meridian at the equator, repeated (at Cayenne in Guyana) RICHER's experiments on the variation of weights at different latitudes. Although a less gifted astronomer than Godin and a less reliable mathematician than BOUGUER (both his colleagues), he often received the major part of the credit for the expedition, because of his amiable nature and his talent as a writer.

La Hire, Philippe de [Philippe I] (1640–1718) and La Hire, Gabriel-Philippe de [Philippe II] (1677–19)

Astronomer, Philippe I was born in Paris, France, educated as an artist, taught mathematics and architecture, wrote on conic sections. He installed the first transit instrument in the Paris Observatory and produced tables giving the movements of the Sun, Moon and the planets. He conducted experiments in terrestrial magnetism and meteorology, surveyed the French coastline (with PICARD) and participated with his son in the geodesic measurements carried out by JACQUES CASSINI to extend the meridian of Paris north from Amiens to Dunkerque. His son, Philippe II, a dilettante and astronomer, born in Paris, lived and was educated at the Paris Observatory, assisting his father in observations. Father and son were accused of plagiarism by LE FEVRE after publishing ephemerides to which Le Fevre claimed authorship. Philippe II published on observational and physical astronomy but also dabbled in architecture, inventions and other natural sciences.

La Plata Observatory

The most important event in the history of astronomy in Argentina 10 years after the foundation of the OBSERVATORIO ASTRONÓMICO DE CÓRDOBA (1870), was the setting up of the Observatorio de La Plata (LPO) (see figures 1 and 2), officially founded on 22 November 1883. Its first Director was Navy Lieutenant Francisco Beuf, of French origin. Indeed, the LPO's existence was set off by an invitation from the Observatory of Paris to prepare a French–Argentine expedition to Bragado, province of Buenos Aires, to observe the transit of Venus on 6 December 1882.

This expedition was equipped with a 21.6 cm telescope, chronometers, a portable meridian circle and meteorological instrumentation (incorporated soon afterwards into the Observatory). The LPO's observational power was later increased with two transit circles (1886), a 10.5 cm altazimuth telescope, a 83 cm reflector (1890), a 33 cm astrograph (1890), a 43 cm refractor (1894), a Repsold vertical circle, two Repsold transit instruments and a Zeiss comet finder. In 1887, LPO was incorporated to the 'Carte du Ciel' project (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS) to observe the zone of the sky from –23° to –32° through a 33 cm standard astrograph which arrived in La Plata in 1890.

In 1905, LPO became part of the National University of La Plata and its specific objectives widened to cover meteorological, seismic and magnetism studies.

In 1911, Dr William J. Hussey, former director of the Ann Arbor Observatory in Michigan, became Director of LPO. He systematized research and incorporated LPO into the worldwide project of the Astronomisches Gesellschaft (1863) (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS) of surveying all stars down to magnitude 9 from –52° to –82° and, later, from –42° to –82°. It took 25 years to complete this survey (positions of 33 300 stars in six catalogues, A to F). Under Hussey's directorship extrameridian astronomy began. F. Aguilar, an engineer who equipped the Observatory with a spectrograph, took over afterwards. Aguilar was then replaced by the German astronomer JOHANNES HARTMANN in 1920 who continued Hussey's work, developing a theory on novae and discovering that the minor planet Eros is a non-spherical rotating body. In 1927 Dr B. H. Dawson, a Michigan graduate, started observing visual double stars and, on 8 November 1942, he discovered Vela's nova.

Figure 1. The French-style main building of La Plata Observatory.

Figure 2. Reading room of La Plata Observatory library.

During Aguilar's second period as director (1934–1943), Dr A. Wilkens (who started celestial mechanics studies) and H. Wilkens (stellar statistics) — both German, Dr R. Cesco and Dr E. Gaviola joined LPO staff. Dr A. Wilkens and R. Platzeck together with J. Sahade and C. Cesco undertook the measurement of stellar temperatures in double systems. Dr Livio Gratton and Dr P. Sconzo — both Italian — also joined the staff. The former led research on binary, Cepheid and giant K-type stars, while the latter started an observational program to refine the orbits of asteroids, many of them having been discovered then. In 1935, LPO offered PhD degrees in astronomy for the first time in the country.

By the 1950s Dr Jorge Sahade (IAU president 1985–1988) recommended the acquisition of a 2.15 m telescope like that to be installed in Kitt Peak by the ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY. Surprisingly enough, the telescope was acquired but it saw first light in 1986 when, through an agreement among the Universities of La Plata, Córdoba and San Juan and the Research National Council (CONICET), it was set up in Calingasta Valley (province of San Juan), becoming a national observing facility: the Leoncito Astronomical Complex, CASLEO (see SOUTH AMERICAN ASTRONOMY).

Binary statistics and systematic spectroscopy in open clusters started by the end of the 1950s, conducted by Dr C. Jaschek (later on, Director of STRASBOURG OBSERVATORY and the CDS). By the 1960s the construction of a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

photometer allowed Dr A. Feinstein to perform photometric observations on southern open clusters.

In 1971 LPO installed a Danjon astrolabe in Río Grande, Tierra del Fuego, through an agreement between the University of La Plata, CONICET, Tierra del Fuego Government and the Navy Hydrology Service. Again via agreement with the Navy Hydrology Service and the Navy Observatory of Washington, a zenithal photographic tube was also installed in the Navy Base of Punta Indio, province of Buenos Aires. LPO discontinued astronomical observations in the 1970s because of city-light pollution. Since then, observational facilities have been provided by Chilean observatories and CASLEO.

Today — as ever since 1905 — research and the teaching of astronomy are the LPO's main objectives. It plays a leading role in the Argentine part of the GEMINI project and most of its members actively collaborate with researchers all over the world. Over 55 staff members are working on a variety of topics including galactic dynamics, celestial mechanics, stellar evolution, radioastronomy and extragalactic reference systems. Recently, a vigorous GPS development has taken place. Funds for research are mainly provided by official agencies such as CONICET.

Laboratory and Space Measurements of the Effects of Gravity

Early philosophers such as Aristotle tried to describe the motion of bodies in the Earth's vicinity with concepts that confused the topics of dynamics (the motion of a body under any external force) with the nature of the force (gravitation) itself. The teaching that followed this doctrine lasted until the mid 1600s when difficulties were becoming apparent in explaining, for example, the motion of arrows whose velocity continued after the force that caused their motion was removed. GALILEO GALILEI [1] began experiments in Pisa to investigate the dynamics of material bodies and the properties of motion under what is now known to be the gravitational force. Galileo was successful in showing that much of Aristotle's dogma was contrary to carefully observed experiments. This work inspired NEWTON [2] to apply the mathematics of calculus to problems of celestial mechanics such as the apparent motion of comets. Newton was able to separate the laws of dynamics from those of gravitation, both of which he was able to describe in simple mathematics with high precision.

The dynamics of a particle of mass M, moving under an external force, F, was described by the vector equation for the acceleration A as

$$\boldsymbol{F} = M\boldsymbol{A}.$$

It was Newton's conjecture that the acceleration, and not the velocity as the Aristotelians had taught, was proportional to the force. This provided the key to understanding dynamics.

Newtonian gravity was encapsulated in the expression for the gravitational force of attraction, F, between two masses, M_1, M_2 separated by a distance r:

$$F = \frac{GM_1M_2}{r^2}.$$

The constant G was determined experimentally by Cavendish [3] and others [4] to be (in modern SI units) 6.67×10^{-11} N m^2 kg^{-2}.

Both Newton and Galileo were aware that if a body were moving under the influence of a gravitational force (rather than any other kind of force, such as electromagnetism for example) then the mass of that body would appear twice in the calculation of the resulting acceleration since the gravitational force is directly proportional to the mass (the 'gravitational mass'), and the acceleration is inversely proportional to the mass (the 'inertial' mass). If every object had the property that its 'gravitational mass' is exactly proportional to its 'inertial mass', then these two values for the mass would cancel and all objects would have the same acceleration, and therefore the same velocity, in an identical gravitational field. Galileo observed this to be true in a number of experiments and Newton systematically explored the equivalence of gravitational and inertial mass for different materials in a series of experiments with pendula of different composition. There was (and is now) no explanation in Newtonian theory of why there are these two separate roles for mass, and several experiments of exquisite precision were carried out in the late 1800s by Eötvös and others to see if the equivalence broke down at some level of precision.

The mathematical statement of the 'Law' of gravitation permitted the accurate calculation of planetary positions, which observations confirmed to the highest precision available. The first deficiencies in this approach began to emerge in 1845 [5] with observations of the slightly elliptical orbit of Mercury, the planet closest to the Sun and therefore the object orbiting in the highest gravitational potential of all the planets. As measurement techniques became more accurate and the baseline for the observation of the secular change in Mercury's orbit became longer and the orbit therefore determined more precisely, the discrepancy became increasingly uncomfortable for Newtonian gravity, despite the fact that the simple inverse square law provides extremely accurate descriptions of most phenomena.

Following the success of EINSTEIN's 'Special Theory of Relativity' [6] in explaining the null result of the Michelson–Morley experiment to measure the effect of the Earth's supposed velocity through an Aether, the next step was to incorporate gravitation within a relativistic theory. This Einstein did with his 'General Theory' in 1916 [7]. At low velocities and small gravitational potentials the new theory had to be consistent with Newtonian gravity in predicting the motion of objects. Rather than leave the equivalence principle as an uncomfortable experimental fact, Einstein raised it to be the underlying concept which illuminated the radical thinking behind his new theory. He proposed that the gravitation was to be understood as a curvature of spacetime created by the presence of mass. Matter moved in this curved SPACETIME in response to the local curvature. Every object in a particular gravitational field experienced the same curvature and hence all objects moved with the same acceleration. The equivalence of inertial and gravitational mass is therefore implicit in the structure of general relativity, and the 'equivalence principle' needs no explanation or resolution.

General relativity cannot yet be understood as the final theory of gravity (see also GENERAL RELATIVITY AND GRAVITATION). The theory has had remarkable success in naturally accounting for the precession of the perihelion of Mercury and predicting the displacement of stellar images close to the Sun but the accuracy to which it has been tested is only a few parts in ten thousand. The most unsatisfactory aspect of the theory is the complete incompatibility with the, now accurately tested, theory of QUANTUM MECHANICS. It is this unresolved problem that is motivating both theorists and experimentalists to test the theoretical predictions of general relativity to higher and higher precision in the search for clues as to where progress can best be made in unifying gravitation with the other fundamental forces of nature.

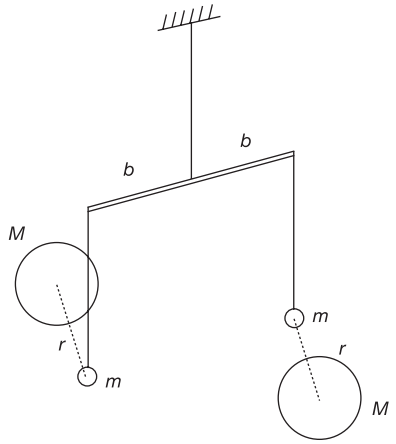

Figure 1. A torsion balance.

Expressed in terms of Newtonian theory, laboratory tests focus on the accuracy of the inverse square law, the value of the gravitational constant, G, and its time derivative, together with evidence that the equivalence principle breaks down at some level of accuracy or for some sets of materials. The dependence of the gravitational force on distance, r raised to the power -2, is appropriate for a truly long-range force, and this implies that any particle postulated as mediating the force (the 'graviton') must necessarily have zero mass, exactly similar to the case of the photon as the mediator of the electromagnetic force. Tests of the accuracy of the inverse square law therefore provide limits on the mass of the graviton. Since general relativity uses the concept of curved spacetime with metric tensors as the mathematical interface between matter and curvature, an expansion of the metric tensor can be made in terms of parameters which express the small deviations from the special relativistic metric in flat spacetime. This Parameterized Post Newtonian (PPN) metric can be used to analyze experiments whose outcome thereby places limits on the various PPN [8] parameters.

Laboratory tests

The gravitational force is extremely weak, nearly forty factors of ten weaker than the electromagnetic force. As a result the gravitational constant is very difficult to measure to high precision. Other factors, such as the inability to shield stray gravitational fields from test masses, make the design and execution of laboratory experiments extremely taxing. Astronomical measurements provide high precision in terms of the dynamics of orbits, but the quantity determined is actually the product of the gravitational constant and the mass of the central object, a number that cannot be determined independently. Most accurate determinations of G use a torsion balance [9] as shown in figure 1.

A fibre with a known torsional constant suspends a balanced pair of test masses. Two methods of executing the measurement are used, the force measurement and the period measurement. In the former, the rotational position of the beam is measured with no source masses close to the test masses which are suspended from the balance. The source masses are moved into the required position with respect to the test masses. As a result of the gravitational force the beam rotates about the torsional axis. A known external force is then used to rotate the beam back to its original position. Accurate measurements of the source masses, the test masses and their separation then permits the determination of G in terms of absolute units. The period method requires the determination of the period of torsional oscillation of the beam both when the source masses are in position and when they are absent. This method of determining G has the advantage that various parameters which are difficult to measure accurately, cancel out in comparing the two periods. This method is not so sensitive to drifts of the apparatus, and time measurements are always more accurate than measurements of angular position because nonlinearity in the detector has much less effect. The difficulties are that the long measurement times place the experiment at risk of substantial environmental changes during the data taking and the nonlinear effects of small oscillations can affect the determination of the oscillation maxima. The outcome of these measurements over a period of 150–200 years is that the constant of gravitation is known only to an accuracy of a few parts in 10 000: a very poor level of accuracy compared with other fundamental physical constants. Some part of this inaccuracy lies in the difficulty of determining in an absolute sense the mass and geometry of the test masses used as the source of the gravitational force. If the unification of physical forces occurs at the theoretical level, it may well be important to have accurate values for these fundamental constants to test the validity of any proposed unification scheme, and this motivates efforts to measure G.

Space and ground tests of general relativity and the equivalence principle

A direct prediction of general relativity is that clocks will be affected by the gravitational potential in which they are located, as measured by observers located at infinite distance from any gravitating masses. The first demonstration of this effect was published by Pound and Rebka [10, 11], using the Mössbauer effect to generate a very narrow absorption line as the detector of the frequency shift. The resulting reduction in frequency (redshift) of the ^{57}Fe gamma rays from a source at the top of a tower some 20 metres high was exactly in accordance with Einstein's prediction. This experiment is now interpreted as a demonstration of the equivalence principle, to a reasonably high degree (about 1%), though not to the accuracy already achieved by Eötvös and colleagues. In 1979 Vessot and Levine [12] repeated the gravitational redshift experiment in space using a hydrogen maser on a Scout rocket. The result again

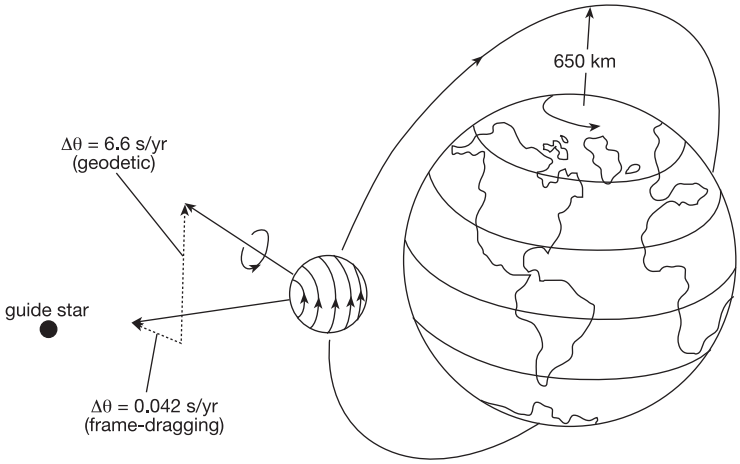

Figure 2. Schematic representation of the 'laboratory test' to be performed by Gravity Probe B.

agreed with the predictions of Einstein's general theory of relativity to about one part in 10^4.

Since the equivalence principle lies at the very foundations of general relativity, various schemes have been devised to extend the accuracy beyond that possible on the ground. Worden [13] has proposed an experiment which, in principle, repeats Galileo's famous Tower of Pisa comparison of the rate of fall of masses of different composition. The generic name for the experiment is STEP, the Satellite Test of the Equivalence Principle. The two test masses are made as concentric cylinders which can slide along, without touching, a linear superconducting bearing. The axis of the bearing is maintained in the plane of the orbit and fixed in inertial space. When the axis is pointing towards the Earth the two masses are attracted in that direction and the experimental apparatus can measure the relative motion of the masses to about one part in 10^{18}. Space provides an excellent environment for such precision experiments. The high vacuum and cryogenic requirements can be met with modern technology, and the absence of interfering gravity gradient signals is extremely important.

A number of subtle effects were predicted by the general theory of relativity [14] and these include departures of spinning particles from simple motions, and more complex behaviour of spinning particles orbiting spinning masses. Beyond description by Newtonian dynamics, these effects are related to the properties of 'parallel transport' in a curved space and the dragging of the local spacetime coordinate system by the spinning central mass. Observation of such motions would test much more of the detailed mathematical structure of general relativity than is possible simply from the motion of non-spinning test particles. The precision required to test general relativity by searching for, and measuring, these non-Newtonian effects has been beyond the available technology until the 1980s. The development of cryogenics, low noise electronics, quantum detectors and space platforms has now brought general relativity within the grasp of experimental physics although the techniques required are some of the most challenging uses of modern technology. The GRAVITY PROBE B experiment [15] sets out to perform the first 'laboratory test' of the general relativistic equations for spinning particles and is shown diagramatically in figure 2 (see also GENERAL RELATIVITY: SOLAR SYSTEM EXPERIMENTS).

This is due for launch in 2001 on a NASA rocket which will place the cryogenic payload in a polar orbit at an altitude above the Earth of 650 km. In the experimental package a spinning rotor is used as the test particle. Manufactured with exquisite precision to avoid disturbing forces created by any imperfections, the rotor is set spinning in such a way that the angle between its rotational axis and the fixed stars can be measured as the experiment proceeds. According to general relativity the spin axis should move slowly with respect to the coordinate frame defined by the stars due to two effects. The Fermi–Walker transport of the spin vector in space curved by the presence of the Earth will cause a drift of the spin axis by 6.6 arcseconds per year in the plane of the orbit. In addition to this, the spin of the Earth drags the coordinate frame around in such a way that there is a motion perpendicular to the orbit of 0.042 arcseconds per year, and the experiment is planned to measure this latter effect to an accuracy of about 1%.

Conclusions

By extending the laboratory into space, tests of our understanding of the gravitational force can be made with a precision which should, eventually, point the way to a resolution of the incompatibility of general relativity and quantum mechanics.

Lacaille 9352

A red dwarf star (spectral type M2–M3V) of apparent magnitude 7.35, situated in the constellation Piscis Austrinus, close to the border with Sculptor and about 6° south of Fomalhaut. It is the ninth closest star, at a distance of 10.7 light-years, parallax 0.304″; its absolute magnitude is 9.8. It is especially significant for having the fourth largest known proper motion, 6.896″ per annum. Stars of such high proper motion are of great value in studies of stellar distribution, and especially of star streaming and galactic rotation. Unfortunately they are very few—only 45 star systems are known with annual proper motions greater than 2″, all within a radius of 96 light-years of the Sun. They range in apparent magnitude from −0.05 to 13.31; only 14 are visible with the unaided eye. They are reasonably well distributed around the sky, but this is a regrettably small number of points of reference on which to construct a model of stellar motions. Thus apparently insignificant stars such as Lacaille 9352 play a major role in astronomical research.

Lacaille, Abbé Nicholas [Nicolas] Louis de (1713–62)

Astronomer, born in Rumigny, France. From 1750 to 1754 he led an expedition to the Cape of Good Hope, where he was the first to measure the curvature of the Earth in South Africa, and, with a small telescope, compiled a still-used catalogue of nearly 10 000 southern stars. In the course of his survey he discovered and listed 50 nebulous objects (eight are now regarded as non-existent). He classified his objects in three categories, foreshadowing the modern astrophysical interpretation: Lacaille I: nebulae; Lacaille II: nebulous star clusters; Lacaille III; nebulous stars. In his *Atlas*, he named 15 southern constellations unseen by classical astronomers: Antlia, Caelum, Circinus, Fornax, Horologium, Mensa, Microscopium, Norma, Octans, Pictor, Pyxis, Reticulum, Sculptor, Telescopium, and renamed the constellation Musca.

Lacerta

(the Lizard; abbrev. Lac, gen. Lacertae; area 201 sq. deg.) A northern constellation which lies between Cygnus and Andromeda, and culminates at midnight in late August. It was introduced by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* of 1687. Hevelius also gave it the alternative name of Stellio (the Stellion—a newt with star-like dorsal spots found along the Mediterranean coast), but this was seldom used. A few years earlier, in 1679, the French architect and celestial cartographer Augustin Royer had depicted a new constellation Sceptrum (the Sceptre—representing the French sceptre and hand of justice, in honor of Louis XIV), which culminated directly overhead as seen from Paris, in approximately the same position, but this was not widely accepted and was soon replaced by Hevelius' Lacerta.

A small, inconspicuous constellation, the brightest stars in Lacerta are α Lacertae, magnitude 3.8, and 1 Lacertae, magnitude 4.1. The Milky Way cuts across the northern part of Lacerta and the constellation contains several open star clusters, including NGC 7243, which consists of several dozen stars of magnitude 8.5 or fainter. Also in Lacerta is BL Lacertae, the variable nucleus (range 12.4–17.2) of a distant elliptical galaxy and the type object of its class.

See also: BL Lacertae objects.

Lada Terra

One of the three large upland regions of Venus (the other two being Aphrodite Terra and Ishtar Terra), situated in the planet's southern hemisphere and centered at 54.4 °S, 17.5 °W. In its greatest dimension it measures 8614 km. It takes its name from a Slavic goddess of love. Like the other upland regions, Lada Terra is covered with tesserae: criss-crossing troughs and ridges. Lada is less elevated than the other main upland regions, and though extensive is less clearly delineated. It lacks the prominent peaks and rifts that characterize the others.

Lagoon Nebula (M8, NGC 6523)

An emission nebula in the constellation Sagittarius, position RA 18^{h} 03.8^{m}, dec. -24° $23'$. At sixth magnitude and measuring $90'$ by $40'$ it is one of the most prominent nebulae in the sky. A bright feature in the central region is known from its shape as the Hourglass Nebula. It contains the star cluster NGC 6530, and is illuminated by a pair of blue giant stars, 7 and 9 Sagittarii. The lanes of dark nebulosity that cross the Lagoon are what give it its name.

Lagrange, Joseph-Louis (1736–13)

Mathematician, born in Giuseppe Lodovico Lagrangia in Turin, Sardinia-Piedmont (now Italy), in a family of modest means. As he said: 'If I had been rich, I probably would not have devoted myself to mathematics'. Contrast with GERHARD HERZBERG. As a young man, he published work on the calculus of variations, developed a theory of dynamics based on the principle of least action, fluid mechanics (where he introduced the *Lagrangian function*) and the orbits of the Moon, Jupiter, its moons and Saturn. A protégé of EULER, he succeeded him as director of mathematics at the Berlin Academy of Science, and worked with him on the three-body problem, the motion of the Moon, perturbations of the orbits of comets by the planets, the stability of the solar system and other mathematical problems. At the age of 51 he moved to Paris, where he was acclaimed as a French mathematician through the publication of *Mécanique Analytique*. This work summarized all the work done in the field of mechanics since the time of NEWTON, using differential equations to transform mechanics into the branch of mathematical analysis that it is today. He was threatened by the events of the Reign of Terror, being vulnerable as a foreigner, but was saved by the intervention of Lavoisier, who himself came under suspicion and was guillotined.

Lagrangian Points

Five neutral points (points at which an object experiences no net gravitational force), in the combined gravitational field of two massive bodies which are orbiting their center of mass, at which an object of much smaller mass can exist in equilibrium. They are so named because Joseph-Louis Lagrange in 1772 was the first to find them as solutions to a restricted case of the three-body problem. Three of the points lie on a line joining the centers of the two massive bodies, M_1 and M_2, assumed for simplicity to be in circular orbits. The *inner Lagrangian point*, denoted by L_1, lies between M_1 and M_2, while L_2 and L_3, the *outer Lagrangian points*, lie on either side. The other two Lagrangian points, L_4 and L_5, are in the orbit of M_2 about M_1, respectively 60° ahead of and behind M_2 in its orbit. L_4 and L_5 therefore form equilateral triangles with M_1 and M_2. A body at L_1, L_2 or L_3 is in unstable equilibrium, very prone to gravitational perturbations, but a body at L_4 or L_5 is less prone to perturbations and has long-term orbital stability.

In practice, the situation is complicated by the ellipticity of real orbits and the presence of gravitational perturbations. In the solar system the best example of bodies in stable orbits at Lagrangian points are the Trojan asteroids at the L_4 and L_5 points of Jupiter's orbit around the Sun. Perturbations by the other planets, notably Saturn, make each Trojan oscillate back and forth between points about 45° and 80° ahead of or behind Jupiter. One Martian Trojan is known, orbiting near Mars's L_5 point. A *halo orbit* is an orbit around a Lagrangian point. The Solar and Heliospheric Observatory (SOHO) was placed in a halo orbit around the Earth's inner Lagrangian point, L_1, between the Earth and the Sun.

Lalande, Joseph-Jérôme Lefrançais de (1732–1807)

Astronomer, born in Bourg-en-Bresse, France. In what was one of the first internationally coordinated scientific campaigns, to determine the Moon's parallax, he was sent in 1752 to Berlin by the French Académie des Sciences. Other astronomers took up positions at six other sites located on more or less the same meridian from Stockholm to the Cape (where Lalande's colleague LACAILLE was located). They observed the Moon (and indeed Mars) simultaneously against its background of stars, and, knowing their mutual distance (in kilometers), they were able to use the method of triangulation in order to determine the Moon's distance. He edited *La Connaissance des Temps* the French almanac, and became professor of astronomy in the Collége de France, and later director of the Paris Observatory. His chief work is *Traité d'Astronomie* (1764), and he also produced a comprehensive star catalog, recording the planet Neptune on two occasions before its discovery without recognizing that it was not a star.

Lambert, Johann Heinrich (1728–77)

Mathematical physicist, born in Mulhouse, Alsace, France, proved that pi is irrational, devised techniques for photometry (the *lambert*, the unit of light intensity, is named after him). He wrote on non-Euclidean geometry, the theory of cartography, and perspective in art. *Lambert's problem* in orbital dynamics is: given a planet A at a given time and planet B at a later time, with what velocity to launch a projectile to get from A to B by orbiting under the influence of the Sun? This is the fundamental question of interplanetary space travel. When asked by King Frederick II in which science he was most proficient, Lambert claimed: 'All'!

Lamont, Johann von (1805–79)

Astronomer, born in Braemar, Aberdeenshire, Scotland, took German nationality, and became professor of astronomy at Munich. Determined the orbits of moons of Saturn and Uranus, worked on terrestrial magnetism, writing a handbook on the subject (1849); discovered that the magnetic field of the Earth fluctuates in a period of 10 years. Von Lamont recorded Neptune on at least three occasions over a four-day period just before its discovery by Galle, and perhaps should have recognized its motion, but did not.

Langren [Langrenus], Michael Florent van [Michael Florentius] (c. 1600–75)

'Spherographer', i.e. astronomer, cartographer, geographer and engineer, born in Amsterdam (probably), into a prominent Belgian family of map- and globe-makers. Tried to determine longitude by predicting phenomena on the Moon (such as the illumination and shadowing of lunar mountains) that could be observed from all points of the Earth and used as clocks. In the course of this work, he prepared lunar maps, including views of the Moon on a daily basis in its cycle. In the hope of patronage, he named the lunar features with the names of prominent figures, such as Pope Innocent X, and royalty. The Infanta Isabelle Claire Eugenie appears three times: a mountain Eugeniae (in Mare Belgicum), Mare Eugenianum, and a mountain Isabellae (in Mare Eugenianum). Became 'Mathematician and Cosmographer' to King Philip IV of Spain.

Laplace, Pierre-Simon (1749–1827)

Celestial mechanician, born in Beaumont-en-Auge, Normandy, France, became professor of mathematics at the Ecole Militaire in Paris, examining the cadet Napoleon Bonaparte. This position made Laplace well known to people in positions of power, which he opportunistically exploited, becoming, under Napoleon, Minister of the Interior (Napoleon soon removed him from office 'because he brought the spirit of the infinitely small into the government'.) He researched probability theory, the calculus, and celestial mechanics. His work was interrupted by the Reign of Terror. Even though, wisely, self-exiled from Paris, Laplace, as a member of the metrication committee of the Académie des Sciences was consulted about rationalization of the calendar and metrication of angles and did not demur with the Revolutionary proposals, although he knew they were impractical and even incorrect. As more stable times returned, Laplace became head of the Paris Observatory, and was criticized for 'neglecting all the observations except those needed for his formulas'. He presented the *Laplace nebular hypothesis* in *Exposition du Systeme du Monde* (1796), that viewed the solar system as originating from a large, flattened, slowly rotating cloud of hot gas. He also expressed another remarkably modern view, of the impact of comets on the Earth: 'The small probability of collision of the Earth and a comet can become very great in adding over a long sequence of centuries. It is easy to picture the effects of this impact on the Earth. The axis and the motion of rotation have changed, the seas abandoning their old position. . . , a large part of men and animals drowned in this universal deluge, or destroyed by the violent tremor imparted to the terrestrial globe'. The *Exposition* was an introduction for Laplace's most important, five-volume work *Traité du Mécanique Céleste*, which set up the differential equations of dynamics, solving them to describe the motion, including the orbits of the planets, the rotation and shape of the Earth and the tides. The book contains what is now called *Laplace's equation* (in fact, known earlier). Laplace explained that 'I have sought to establish that the phenomena of nature can be reduced in the last analysis to actions at a distance between molecule and molecule, and that the consideration of these actions must serve as the basis of the mathematical theory of these phenomena'. In Laplace's later work *Théorie Analytique des Probabilités*, and with this philosophy in mind, he applied probability theory to errors in observations, the determination of the masses of Jupiter, Saturn and Uranus, surveying and geodesy.

Large Binocular Telescope

The Large Binocular Telescope (LBT) project is a collaboration to build a twin interferometric telescope between institutions in Arizona, Germany, Italy and Ohio. Arizona includes astronomers at the University of Arizona, Arizona State University and Northern Arizona University. Germany is represented by the LBT Beteiligungsgesellschaft which is composed of the Max-Planck-Institut für Astronomie in Heidelberg, Landesstenwarte Heidelberg, the Max-Planck-Institut für Radioastronomie in Bonn, the Max-Planck-Institut für Extraterrestrische Physik in Munich and the Astrophysikalisches Institut Potsdam. The Italian astronomical community is represented by the Osservatorio Astrofisico di Arcetri in Florence. Partners at individual institutions include Ohio State University in Columbus, the University of Notre Dame and the Research Corporation in Tucson.

The two 8.4 m borosilicate honeycomb primary mirrors for LBT are being cast at the STEWARD OBSERVATORY Mirror Laboratory. The baseline optical configuration of LBT includes adaptive infrared $f/15$ secondaries of a Gregorian design. The interferometric focus combining the light from the two 8.4 m primaries will reimage the two folded Gregorian focal planes to three central locations. The telescope structure is being fabricated in Italy. After pre-erection in the factory, it will be shipped to Arizona towards the end of 2000. The enclosure is being built on Mount Graham in southeast Arizona.

Large Hot Subdwarfs and Extreme Horizontal Branch Stars

The hot subdwarf stars were first identified by their extremely blue colors in early field and cluster color-select photometric surveys (Humason and Zwicky 1947). Spectroscopic studies soon followed (Münch 1958, Greenstein 1965). From the cluster studies, it was quickly recognized that hot subdwarfs must have lower luminosities than main sequence stars of the same blue color, i.e. O and B stars, and it was Greenstein who first labeled them 'hot subdwarfs'. They were divided into subdwarf O (sdO) and subdwarf B (sdB) classes based on their spectral features, with the hotter sdO stars showing strong He II λ 4686 absorption and very weak or absent He I absorption, while, in the cooler sdB stars, the He II feature was lacking or very weak, and the neutral helium lines showed a broad range of strengths. Model atmosphere analyses of their spectra have confirmed their high effective temperatures and surface gravities, and their smaller radii and luminosities.

In recent years, the sdB stars have become firmly identified with the horizontal branch (HB) phase of post-main-sequence stellar evolution, in which stars derive their energy from the burning of helium into carbon (see HORIZONTAL BRANCH STARS). The relationship is seen most clearly in metal-poor globular clusters (GC), where the cluster blue horizontal branch (BHB) stars often are seen to have an extended blue 'tail', or extended horizontal branch (EHB). However, not all metal-poor clusters exhibit this phenomenon, and the existence or absence of blue tails in GC HBs is a mystery which could be strongly connected to the process that forms sdBs. Pairs of clusters such as M3–M13 (famous so-called 'second parameter' pairs) are important for learning about the origin of sdB stars. A review is given by Moehler (1999). Photometrically and spectroscopically, the cluster EHB stars are found to be indistinguishable from their field sdB counterparts. In this article, the sdB and EHB designations are used interchangeably.

To set the stage for a discussion of the sdB stars, we first briefly review the main evolutionary stages of intermediate-mass stars, i.e. those with initial masses of about (1–8)$M_{\odot}$. These stars ultimately will end their lives as white dwarfs (WDs). We take as a representative example a star having an initial mass equal to that of our own Sun, with the reminder that initially more massive stars will evolve on shorter timescales.

Evolution of intermediate-mass stars

Stellar birth and early evolution

Stars begin their lives as contracting condensations in massive clouds of gas and dust. Their compressed central regions eventually become hot and dense enough for hydrogen to undergo nuclear fusion reactions that transform it into helium, liberating vast amounts of energy in the process. After central hydrogen ignition, the star settles into its first stable stage of STELLAR EVOLUTION, the hydrogen-burning main sequence. Our own Sun is in this stage, which for stars having a similar initial mass lasts for some 10^{10} yr. In the central 10% of the mass (the core), the temperature and density are high enough to sustain nuclear burning reactions, and hydrogen is steadily converted into helium. The energy is released both as light and as kinetic energy of the gas particles (that is, as heat), both of which serve to stabilize the collapse of the star against its own self-gravity. At the end of the main sequence phase, the available hydrogen in the core is completely converted into inert helium. The core material is not hot or dense enough to initiate helium burning, and, lacking a source of fuel, fusion reactions within the core cease.

Red giant branch evolution

Without the continuing generation of heat and pressure from the now-extinct fusion reactions, the stellar core can no longer support itself against its own gravitational pull, and it begins a slow, steady contraction, becoming even hotter and denser as it does so. For intermediate-mass stars like the Sun, the core is ultimately able to stabilize itself owing to the onset of quantum-mechanical electron degeneracy, which provides the pressure necessary to balance the star's self-gravity. Hydrogen does continue to burn in a thin shell around the now-degenerate $0.1M_{\odot}$ inert helium core, and the star enters the red giant branch (RGB) stage of evolution (see RED GIANT STARS).

The RGB is so named because the extremely high temperatures at the surface of the core drive shell hydrogen burning at an even higher luminosity than the previous stage of core hydrogen burning. The increased energy flow causes the outer, hydrogen-rich envelope to expand and cool, and hence the star moves up and to the right in the H–R diagram. As shell hydrogen burning continues to add helium to the core, the peculiar properties of the degenerate matter result in the core shrinking as the mass grows. The core grows even hotter as a result, shell hydrogen burning proceeds at an even faster rate, and the stellar luminosity rises even further. The star thus steadily 'ascends' the RGB as the core continues to grow in mass. The star remains in this stage of evolution for about 10^9 yr, i.e. about 10% of the time it spends on the main sequence. We note that the termination of this phase of evolution is not determined by the exhaustion of a nuclear fuel as it was at the end of the main sequence phase, but rather by the ignition of a new nuclear fuel, helium.

Horizontal branch evolution

When the inert, degenerate helium core mass reaches $\sim$(0.45–0.50)$M_{\odot}$, the temperature and density become high enough to initiate a second stage of nuclear burning—the so-called 'triple-alpha' (3α) process—wherein three helium nuclei are fused to a single nucleus of carbon. The re-ignition of the central 'furnace' provides sufficient heat and pressure to lift the electron degeneracy and return the core material to a 'normal' condition, where the pressure is determined through an ideal gas equation of state. The star

once again is able to hold gravity at bay, and it commences a second stable phase of energy production through the fusion of helium to carbon in the core. Hydrogen continues to burn in a shell surrounding the helium-burning core, with each energy source providing approximately half of the star's total luminosity. This phase of evolution has been termed the 'horizontal branch' (HB), since the V magnitude of stars in this phase is about the same for a broad range of effective temperatures ($T_{\rm eff}$). This results in a flat or horizontal distribution in the H–R diagram, at least for all but the hottest blue HB stars. HB stars remain in this stage of evolution for about 10^8 yr, i.e. about 10% of the time they spend on the RGB. At the end of the HB phase, helium is exhausted in the core, having been converted to carbon and oxygen, the latter having been produced by α capture onto carbon.

Subsequent evolution through the asymptotic red giant branch and PLANETARY NEBULA phases, and the star's final WHITE DWARF phase, are discussed elsewhere in this encyclopedia.

Observational characteristics of EHB stars

Optical colors and spectra

In EHB stars, the optical broadband colors are quite blue, $B-V \sim -0.3, U-B \sim -1.0$, so that the detection efficiency is very high in ultraviolet-excess color surveys. However, a significant fraction (15–20%) of hot subdwarfs are found in binaries with bright main sequence or subgiant companions which redden the optical colors. The optical spectra are characterized by blue continuua, with broad, shallow hydrogen and diffuse helium absorption lines (compared with main sequence B stars). As previously noted, the distinction between the sdO and sdB subclasses of hot subdwarfs has been based on the presence and strength of the H, He I and He II absorption lines.

Recently, Jeffery *et al* (1997) carried out spectroscopy of hot subdwarfs previously classified as 'helium-rich subdwarf B stars' from low-resolution spectra. They found a wider range in He II/He I and He/H ratios than previously found in the class. Their revised classification scheme for helium-rich hot subdwarfs is based on higher-resolution, high signal-to-noise ratio (S/N) spectra and can be extended to include all hot subdwarfs with spectra dominated by H, He I or He II.

Ultraviolet spectra and abundances

The ultraviolet (UV) spectra of sdB stars show numerous photospheric lines of heavy elements with high excitation, such as N III, C IV, Si IV and others, usually very sharp compared with the lines of hydrogen and helium. Additional weak, very sharp features are seen in the optical spectra at very high dispersion and S/N. The elemental abundances are modified by diffusion and, possibly, mass-loss processes in the hot, higher-gravity atmospheres, with helium typically underabundant, and with carbon and silicon underabundant. Nitrogen usually appears normal. The modified abundance patterns obscure relationships between sdBs and their progenitor stars and make their evolutionary history more difficult to establish.

The photometric and spectroscopic observational history of hot subdwarfs is rich, if brief; a summary is given by Saffer and Liebert (1995).

Astrophysical properties

Atmospheric parameters

In the first comprehensive analysis of hot subdwarfs, Greenstein and Sargent (1974) found that most sdB stars fell into a $T_{\rm eff}$ range of 25 000–35 000 K and had a range of surface gravities log g between 5 and 6. They argued that the HB and EHB stars had similar structures, with helium-burning cores and hydrogen-rich envelopes. The EHB stars, however, had such thin envelopes ($\lesssim 0.01 M_\odot$) that they could not sustain a hydrogen-burning shell, which in normal HB stars produces approximately half of the stellar luminosity.

The Palomar Green (PG) Survey (Green *et al* 1986) revealed large numbers of hot subluminous stars. The new, large sample prompted fresh analyses to determine effective temperatures, surface gravities and chemical abundances (e.g. Moehler *et al* 1990, Saffer *et al* 1994, Saffer and Liebert 1995 among others; see Saffer and Liebert 1995 for a summary). Complementary programs in the southern hemisphere, the Edinburgh–Cape (EC) and Hamburg Schmidt (HS) surveys, have also identified large numbers of hot subdwarfs at high galactic latitudes (see also BLUE STARS AT HIGH GALACTIC LATITUDES). The compilation of Kilkenny *et al* (1988) lists 1225 spectroscopically identified hot subdwarfs, many of which now have estimated temperatures and surface gravities from modern model atmosphere analyses. The addition of hot subdwarfs from the EC and HS surveys will undoubtedly significantly increase these numbers.

Evolutionary status

Modern theoretical evolutionary calculations of HB and EHB sequences make predictions of effective temperatures and surface gravities for a range of core and envelope masses (Sweigart 1987, Caloi 1989, Dorman *et al* 1993). Comparisons with observational estimates for both the field sdB stars and globular cluster EHB stars indicate that the bulk have a very narrow range of helium core masses near $0.5 M_\odot$ and very thin hydrogen-rich envelope masses $M_{\rm env} < 0.01 M_\odot$.

Figure 1 shows the distribution of a large-scale spectroscopic survey of high-latitude B stars in the $T_{\rm eff}$–log g plane, where the open symbols represent the high-gravity subdwarfs (Saffer *et al* 1997). The helium abundance is indicated by the type of symbol, being strongly depleted, mildly depleted, normal or enhanced for open circles, triangles, squares or stars, respectively. The filled symbols represent halo B-type star candidates. Proceeding from low to high surface gravity, the two solid curves are post-AGB evolutionary sequences labeled with the core mass (Schönberner 1983), the dot-dashed curve is the population I zero-age main sequence (ZAMS) (Allen

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

1973), the diagonally curving dashed and dotted lines are $0.5M_{\odot}$ core helium-burning HB stars with varying overlying hydrogen-rich envelope masses (Sweigart 1987, Caloi 1989), and the solid, nearly horizontal curve at $\log g \gtrsim 6.0$ is the helium ZAMS (Paczyński 1971). The latter is labeled with the mass of the helium-burning core (see HERTZSPRUNG–RUSSELL DIAGRAM, POPULATION I STARS). The undulating curves lying between the post-AGB and HB tracks are post-core helium exhaustion stars where helium burning continues in a shell around an inert carbon–oxygen core (Caloi 1989).

The theoretical sequences also show that following the exhaustion of helium in the core, EHB stars are unable to ascend the asymptotic giant branch (AGB) because their thin hydrogen envelopes cannot sustain a hydrogen-burning shell. Instead, they move to higher temperatures and luminosities for durations of about 10% of their core-helium-burning lifetimes, as they undergo helium shell flashes in the region of the H–R diagram occupied by the sdO stars. Thus, at least some of the sdO stars appear to be the direct descendents of the EHB stars. Some low-mass post-AGB evolutionary tracks also pass through the sdO region (Schönberner 1983), and mergers of pairs of He WDs also may produce sdO stars (Bailyn and Iben 1989).

Chemical abundances

Detailed calculations of radiative acceleration on helium and heavier elements suggest that some elements can be supported against gravitational settling in the hot, high-gravity atmospheres of sdB stars (Lamontagne *et al* 1985, 1987, Michaud *et al* 1985, 1989; Bergeron *et al* 1988; see also CHEMICAL COMPOSITION OF STARS). Observations generally support this picture, as hot subdwarfs do show markedly non-solar chemical abundance distributions, presumably as the result of diffusion processes (see also SOLAR ABUNDANCES). However, the observed detailed abundance patterns are generally not in agreement with theoretical predictions. For example, silicon is predicted to be supported in sdB stars but is found to be underabundant, and helium should be extremely depleted (so that helium absorption lines should not be detectable) but in general is found to be underabundant only by a factor of 10. These results suggest that other particle transport processes, such as a weak stellar wind, operate in subdwarf atmospheres. A review is given by Fontaine and Chayer (1997), and previous abundance analyses from UV spectroscopy have been reviewed by Heber (1998).

The EC 14026 stars

In 1997 a new class of pulsating star was discovered. These stars, designated the EC 14026 stars after the prototype, are pulsating subdwarf B stars with $T_{\rm eff} \sim 35\,000$ K and $\log g \sim 6.0$. The multiperiodic oscillations have periods $P \sim 120$–500 s and amplitudes typically less than 1%. Photometric surveys have thus far identified 18 pulsators. Their spectra reveal that several of the hot subdwarfs are binary, having a cooler main sequence or subgiant F or G type star. Apparently constant stars mingle with the pulsators, so that there is no well-defined instability strip. This poses a significant challenge to the Fe opacity bump mechanism proposed to drive the oscillations (Charpinet *et al* 1997). Indeed, new abundances for pulsating sdB stars derived from high-resolution Keck spectra (Heber *et al* 1999, 2000) strengthen the conclusion that the iron abundance is not the sole discriminating factor for pulsation driving. Identification of the modes of oscillation and the driving mechanism will lead to an improved asteroseismological understanding of hot subdwarfs and to better estimates of their masses, rotation rates, physical structure and chemical compositions.

EHB distances, scale height and midplane density

The distribution of EHB stars in the H–R diagram suggests a mass of $0.5M_{\odot}$, and reddening along the line of sight is estimated by comparing the observed and theoretically predicted colors. Combined with the stellar mass and reddening, the derived EHB effective temperatures and surface gravities lead to estimates of heights above the GALACTIC PLANE ($z = d \sin b$) of 1–3 kpc. Assuming an exponentially decreasing density with increasing height above the Galactic plane, early scale height estimates were made using samples with relatively bright limiting magnitudes. The derived scale height z_0 ranged from 180 to 240 pc, indicating membership in the old disk population. Saffer and Liebert (1995) used a deeper, more complete high-latitude sample to derive $z_0 = 500$ pc, implying that the population is significantly older than the bulk of the stars in the old part of the thin disk. Most recently, Mitchell (1998) used a faint ($V \lesssim 18$), pencil-beam sample of field sdB stars to show that a substantial fraction of sdB stars fainter than the limiting magnitudes of the large color-select surveys (PG, EC, HS) belong to the halo population and not that of the old disk. de Boer *et al* (1997) studied the orbits of relatively bright sdB stars ($V \lesssim 14.5$), finding many eccentric orbits. However, none of the stars could be positively halo objects, probably because of the bright limiting magnitude of their sample.

The Kitt Peak Downes Survey (KPD; Downes 1986) in the Galactic plane, similar to the PG Survey both in color-excess criteria and in limiting magnitude, also identified large numbers of hot subdwarfs. The sample is especially well suited for the determination of the EHB midplane space density. Using a $V/V_{\rm max}$ analysis, Saffer and Liebert (1995) estimated the field EHB space density to be $n_0 = 7.5 \times 10^{-7}$ pc^{-3}, compared with previous estimates of 1.5–2 $\times 10^{-6}$ and 4×10^{-6}. Assuming a core helium-burning lifetime $\tau = 1.5 \times 10^8$ yr, the EHB birthrate is then $b = n_0/\tau = 5 \times 10^{-15}$ pc^{-3} yr^{-1}. Current estimates of the local white dwarf birthrate range from 0.5×10^{-12} to 2×10^{-12} pc^{-3} yr^{-1}, that is, the contribution to the local white dwarf birthrate from the EHB channel is just 0.25–1%, compared with previous estimates of about 2%.

Origins and subsequent evolution

The suggestion that hot subdwarf stars might produce the significant amounts of far-ultraviolet (FUV) flux seen

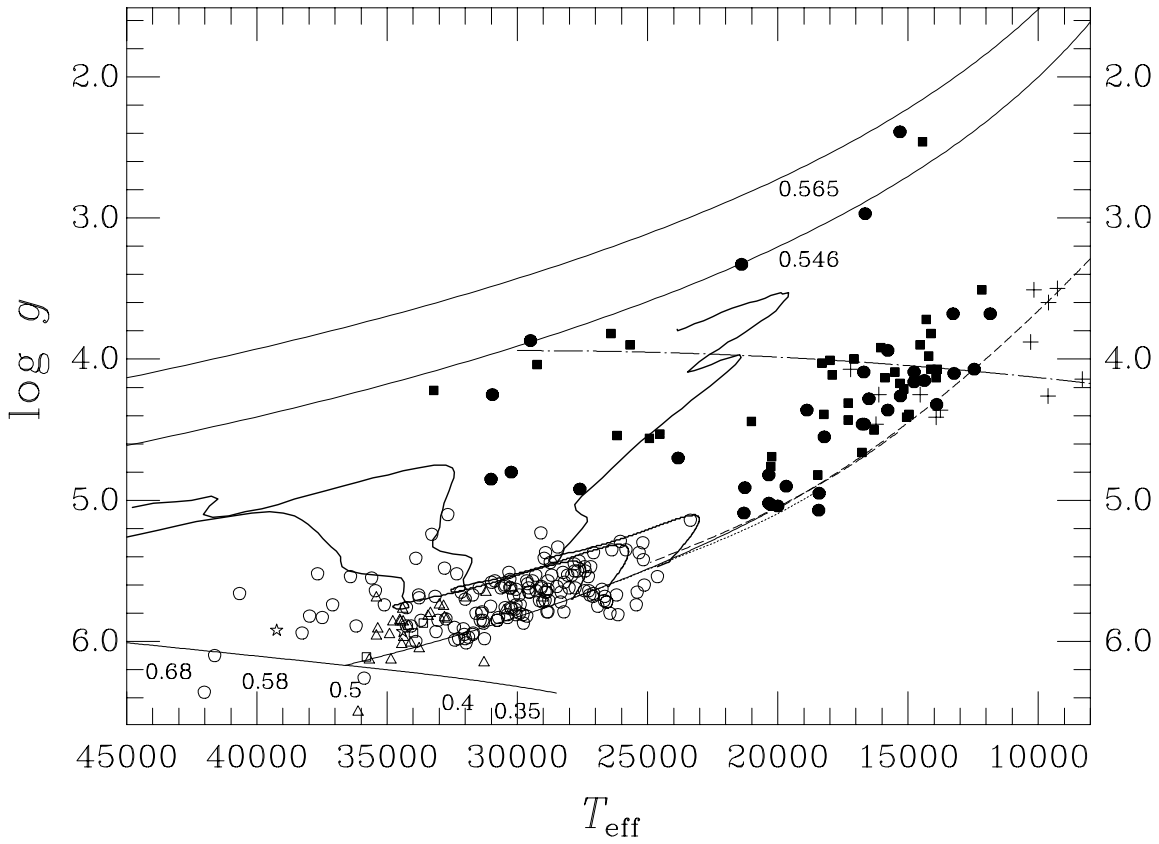

Figure 1. Distribution of a large-scale spectroscopic survey of high-latitude B stars: see text for details.

in many ELLIPTICAL GALAXIES (e.g. Dorman *et al* 1995) as well as their ubiquitous presence in the field have motivated numerous studies to determine their origins. Any proposed mechanisms must be able to reproduce the inferred physical structure of the EHB stars, namely, a helium-burning core of $\sim 0.5 M_{\odot}$ and a very thin ($<0.01 M_{\odot}$) hydrogen-rich envelope. The key problem is how to achieve the critical mass for core-helium ignition while at the same time removing virtually all of the hydrogen-rich envelope.

In metal-poor globular clusters, Reimer's mass loss in single RGB stars can plausibly remove upwards of $0.3 M_{\odot}$ from the hydrogen-rich envelope. In such a stellar population, this is sufficient to completely strip the envelope of the RGB progenitors (low-mass turn-off stars) by the time their cores grow to the critical helium-ignition mass on the RGB. This scenario is more problematic in the field and in younger, more metal-rich GLOBULAR and GALACTIC OPEN CLUSTERS, where the turn-off mass is higher. Some success has been achieved for stars with extremely high metallicities and/or helium abundances.

Alternatively, in CLOSE BINARY STARS, ROCHE LOBE overflow could easily strip the envelope. Mengel *et al* (1976) first investigated this scenario and successfully produced EHB stars, but only for a very narrow range of initial stellar masses and orbital separations. For very close initial separations, the envelope is stripped before the helium core grows to ignition mass, leaving a helium WD. For wide initial separations, helium ignition occurs while a substantial envelope mass remains, producing a normal HB star. Liebert *et al* (1994) found the range of orbital separations producing EHB stars in this scenario to be too narrow to explain the HB morphology of the metal-rich Galactic cluster NGC 6791.

Recent studies of field sdB stars imply a large binary fraction, as revealed both by composite colors and by high-precision radial velocity variations. Green and Chaboyer (1998) showed that sdB stars can be distingushed by their spectroscopic and kinematic properties. Some ∼15–20% of field sdB stars have composite spectra indicating the presence of a cool companion. These either do not vary or have small radial velocity variations indicative of binaries with wide separations (a few AU). A second group of ∼45–50% of the field sdB stars have large radial velocity variations with characteristic timescales of days. These have no obvious visible companions, which are assumed to be WDs. Rarely, the invisible companions are detected through eclipses or reflection effects. The remaining ∼35% of field sdBs are apparently single.

Provided that most field sdB stars are the counterparts of the GC EHB stars, their fate seems certain. Since they

cannot add to their $0.5M_{\odot}$ cores in a subsequent AGB phase, after the short-lived post-EHB phase they seem destined to directly enter the WD cooling sequence, albeit with CO core masses of $\sim 0.5M_{\odot}$, about $0.1M_{\odot}$ less than the average WD. As noted previously, the sdB stars contribute only a very minor fraction to the total WD birthrate.

Unsolved problems

Much progress has been made in the last decade toward the understanding of the astrophysical properties and evolutionary histories of the sdB/EHB stars. The understanding of several key issues remains elusive.

(1) How are hot subdwarfs formed? Evidence increasingly points to a close binary evolution connection, but the details are still sparse. A comprehensive theoretical investigation of close binary Roche lobe overflow and envelope stripping over a wide range of initial stellar masses and initial separations is needed. No such investigation has been undertaken since that of Mengel *et al* (1976). Infrared observations of the apparently single population of field sdB stars would confirm or rule out the existence of low-mass secondaries hitherto undetected. These results would have significant implications for the outcome of the common-envelope phase which all sufficiently close systems must undergo.

(2) Theoretical predictions of the detailed abundance distributions in sdB photospheres remain at odds with the observations. New generations of model atmosphere codes that self-consistently take elemental diffusion and stellar winds into account in calculating the atmospheric structure are now available and should shed new light on this persistent problem. A description of these new codes is given by Dreizler (1999).

(3) The pulsating sdB stars offer a new and exciting asteroseismological window into sdB STELLAR INTERIORS. Detailed abundance distributions of the iron-group elements may help solve the current conundrum of the existence of constant stars in the same temperature and gravity ranges as known pulsators. Iron itself, the suspected opacity source for the driving mechanism, does not seem to be the discriminating factor.

Large Magellanic Cloud

The larger of two nearby companions of the Milky Way Galaxy that can be seen with the naked eye in the southern hemisphere sky and which are named after the Portuguese navigator, Ferdinand Magellan, who observed them in 1519 during his circumnavigation of the world. Located in the constellation of Dorado, at a distance of about 170 000 light-years, the Large Magellanic Cloud (LMC) has an overall diameter of about 35 000 light-years and contains about 10^{10} stars. Its overall mass is between one-tenth and one-twentieth of that of the Milky Way Galaxy. It was originally classified as an irregular galaxy (of type Irr I in the Hubble classification), but, because it has a conspicuous central bar and shows hints of what may be an incipient spiral arm, it is now considered to be an irregular barred spiral, the prototype of a class designated 'Sm'. It contains the Tarantula Nebula, a huge HII region, with a diameter of about 900 light-years, which surrounds a vigorous star-forming region, and is one of the largest HII regions known. The LMC, which contains numerous clouds of gas and dust, young star clusters and supernova remnants, appears to be experiencing a major bout of star formation that was probably triggered by the effects of a close encounter with the Milky Way a few billion years ago.

Large-Scale Plasma Dynamics

Most of the universe is occupied by gas that is electrically neutral but more or less fully ionized, i.e. PLASMA, and permeated by a magnetic field $\boldsymbol{B}$ on a large scale L. The plasma, driven by the energy of the stars, is in a remarkably active, and often suprathermal, state. The coronal mass ejection from the Sun is an example of the active state, while the million degree corona of the Sun is an example of the suprathermal state, giving rise to the dynamical expansion that produces the supersonic SOLAR WIND sweeping out through the solar system. The interstellar gas is powerfully agitated by the intense heating around massive HIGH LUMINOSITY STARS. Expanding SUPERNOVA shells and the CRAB NEBULA are examples of dynamical states, whose shock fronts heat the gas throughout large volumes of interstellar space to suprathermal temperatures of 10^5 K or more, causing the gas to expand up out of the gaseous disk of the Galaxy to contribute to the galactic halo. So a proper formulation of the dynamics of a magnetized plasma is essential for understanding the activity of the Sun and other stars and of the Galaxy.

In a tenuous fully ionized gas the individual electrons and ions gyrate around the magnetic field while being scattered by electrostatic interactions with their neighbors. The cyclotron frequency of the gyration is $\Omega = qB/Mc$ for a particle with mass M and charge q. The cyclotron radius R is $w_\perp/\Omega$ where $w_\perp$ is the velocity of the particle perpendicular to the magnetic field. The electric field of an individual particle is screened off by its neighbors beyond the characteristic Debye length $D = (kT/4\pi Ne^2)^{1/2}$ in a plasma with temperature T and number density N. The effective mean free path for both electrons and ions is approximately (Spitzer 1956)

$$\lambda = \frac{2 \times 10^5 T^2}{N \ln(1.2 \times 10^4 T^{3/2}/N^{1/2})} \text{ cm}$$

This article examines the large-scale bulk dynamics of such plasmas and fields.

With rare exceptions the plasma beneath the surface of a star is collision dominated ($\lambda \ll R$), and the electric current density $\boldsymbol{j}$ required by Ampère's law,

$$4\pi \boldsymbol{j} = c\,\boldsymbol{\nabla} \times \boldsymbol{B}$$

is pushed through the plasma by the electric field $\boldsymbol{E}'$ in the local frame of reference of the moving plasma, where $\boldsymbol{j} = \sigma \boldsymbol{E}'$ and the conductivity σ is approximately 2×10^7 T$^{3/2}$ s^{-1} for ionized hydrogen. The electric field $\boldsymbol{E}'$ in the frame of the plasma moving with velocity $\boldsymbol{u}$ is related to the fields $\boldsymbol{E}$ and $\boldsymbol{B}$ in the laboratory frame by the Lorentz transformation

$$\boldsymbol{E}' = \boldsymbol{E} + \frac{\boldsymbol{u} \times \boldsymbol{B}}{c}$$

on neglecting terms second order in u/c. The current density is automatically regulated to satisfy Ampère's law because of the rapid growth of the electric field,

$$\frac{\partial \boldsymbol{E}}{\partial t} = \boldsymbol{c}\,\boldsymbol{\nabla} \times \boldsymbol{B} - 4\pi \boldsymbol{j}$$

in the direction of any current deficit, with the energy coming from the magnetic field through the induction equation $\partial \boldsymbol{B}/\partial t = -c\,\boldsymbol{\nabla} \times \boldsymbol{E}$. Thus $\boldsymbol{E}'$ continually evolves with changing $\boldsymbol{u}$ and $\boldsymbol{B}$ so that $\boldsymbol{E}' = c\,\boldsymbol{\nabla} \times \boldsymbol{B}/4\pi\sigma$. The energy flow in the frame of the large-scale bulk motion of the plasma is always from the field into the current, as a consequence of the nonvanishing resistivity, and the large-scale dynamics is described by the familiar induction and momentum equations of MAGNETOHYDRODYNAMICS, with $\boldsymbol{\nabla} \times \boldsymbol{E}'$ in the induction equation providing the resistive diffusion of $\boldsymbol{B}$.

In contrast, the mean free path λ in extended stellar atmospheres, in the solar wind, in planetary magnetospheres and in interstellar space (excluding cold dense molecular clouds) is generally large compared with the cyclotron radius R, so the electrons and ions gyrate relatively freely in the magnetic field. The large-scale bulk velocity $\boldsymbol{u}$ of the plasma represents the local mean momentum per unit mass of the individual electrons and ions. The velocity $\boldsymbol{w}$ of a particle relative to the mean motion $\boldsymbol{u}$ represents the thermal velocity, which has zero mean when summed over the local particles.

Consider, then, the bulk dynamics of a plasma and magnetic field in the limit that interparticle collisions can be neglected ($\lambda \gg R$) and the electrons and ions gyrate freely in the large-scale magnetic field $\boldsymbol{B}$. The particle pressure $p_\perp$ perpendicular to $\boldsymbol{B}$ is isotropic about the direction of $\boldsymbol{B}$ as a consequence of the cyclotron motion $w_\perp$, and

$$p_\perp = \frac{1}{2} \sum M w_\perp^2$$

where the sum is over all particles in unit volume. The pressure $p_\parallel$ parallel to $\boldsymbol{B}$ is given by

$$p_\parallel = \sum M w_\parallel^2$$

where the sum is again over unit volume, and $w_\parallel$ represents the thermal velocity parallel to $\boldsymbol{B}$. It should be noted that $p_\parallel$ and $p_\perp$ are not necessarily equal in a collisionless plasma (see COLLISIONLESS PROCESSES IN ASTROPHYSICAL PLASMAS). However, thermal anisotropy and any strong electron conduction velocity (relative to the ions) generally excite plasma oscillations that scatter the particles, pulling the thermal motions toward isotropy ($p_\parallel \sim p_\perp$). Thus, for instance, in the high-speed tenuous solar wind the anisotropic expansion maintains a measurable but limited thermal anisotropy. On the other hand, no significant anisotropy is expected in the quasi-static corona close to the Sun.

Now the bulk velocity of a tenuous plasma with mass density ρ is described by the momentum equation

$$\frac{\partial \rho u_j}{\partial t} = \frac{\partial}{\partial x_k}(-p_{jk} + M_{jk} + R_{jk})$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_k}{\partial x_k} = 0$$

where p_{jk} is the pressure tensor, with diagonal terms $p_\parallel$ and $p_\perp$. Off-diagonal terms represent viscosity, if it is relevant. The Maxwell stress tensor M_{jk} is the usual $-\delta_{jk}B^2/8\pi + B_jB_k/4\pi$, representing the isotropic pressure $B^2/8\pi$ and the tension $B^2/4\pi$ in the direction of the field. The Reynolds stress tensor R_{jk} is $-\rho u_j u_k$, representing compressive stress in the direction of the velocity. That is to say, p_{jk} is the momentum flux of the thermal motions and $-R_{jk}$ is the momentum flux of the bulk motion. This form of the momentum equation follows directly from application of Gauss' theorem to the net momentum transport into a fixed volume V with dimensions small compared with L but sufficiently large that $NV \gg 1$.

Individual particle motions

To proceed further, consider the motion of an individual ion or electron, described by a mass M and charge q. With $L \gg R$ it is sufficient to use the guiding center approximation, in which the particle moves primarily in a circle with cyclotron radius $R = Mw_\perp c/qB \ll L$. The center of the circle—the guiding center—slides freely along the field while it drifts slowly across the field as a consequence of the large-scale variation of the field. The cyclotron motion represents a mean electric current $q\Omega/2\pi$ around the perimeter of the area πR^2, providing a diamagnetic dipole moment $\mu = Mw_\perp^2/2B$ that is a constant of the motion for each particle in the limit of large L/R. The diamagnetic moment repels the particle from regions of strong field with a force $\mu\,\partial B/\partial s$ along the field, where s represents distance along the field. Thus the motion $w_\parallel$ parallel to $\boldsymbol{B}$ is described by

$$\frac{\mathrm{d}w_\parallel}{\mathrm{d}t} = -\mu\frac{\partial B}{\partial s}.$$

It should be noted that in a plasma with isotropic thermal motions ($p_\parallel = p_\perp$) this repulsion from a converging field exactly compensates for the particle concentrating effect $(Nw_\parallel/B)\,\partial B/\partial s$ of the converging field. When $p_\perp > p_\parallel$, the net effect is to push the plasma away from the regions of strong field, whereas, when $p_\perp < p_\parallel$, the converging field lines enhance the plasma in regions of strong field. The isotropic plasma maintains a uniform density along the field, for the reason given.

Consider the force $\boldsymbol{F}$ perpendicular to $\boldsymbol{B}$ applied to the particle. The initial effect is to accelerate the particle in the direction of $\boldsymbol{F}$. That motion provides a Lorentz force and a drift velocity $\boldsymbol{W}$ in the direction $\boldsymbol{F}\times\boldsymbol{B}$, so that the Lorentz force $q\boldsymbol{W}\times\boldsymbol{B}/c$ opposes $\boldsymbol{F}$. The acceleration of the particle falls to zero when $\boldsymbol{W}$ reaches the value $c\boldsymbol{B}\times\boldsymbol{F}/qB^2$ and its Lorentz force cancels the applied $\boldsymbol{F}$. The total displacement ξ in the direction of $\boldsymbol{F}$ is $(Mc^2/q^2B^2)\boldsymbol{F}$ such that the impulse $q\xi\times\boldsymbol{B}/c$ is equal to the final transverse momentum $M\boldsymbol{W}$.

In the presence of an electric field $\boldsymbol{E}_\perp$ the force is $\boldsymbol{F} = q\boldsymbol{E}_\perp$ and the final velocity across the magnetic field is the electric drift velocity $\boldsymbol{u}_\perp = c\boldsymbol{E}\times\boldsymbol{B}/B^2$ independent of the charge and mass of the particle. Every ion and electron takes up the velocity $\boldsymbol{u}_\perp$, so that $\boldsymbol{E}_\perp = -\boldsymbol{u}\times\boldsymbol{B}/c$ and the plasma moves in the frame of reference in which there is no electric field, $\boldsymbol{E}'_\perp = 0$. Thus $\boldsymbol{u}$ represents the bulk motion of the plasma, and the electric field $\boldsymbol{E}$ in the laboratory frame arises because the electric field in the frame of reference of the plasma is zero. Thus the value of $\boldsymbol{E}$ depends on the arbitrary choice of the laboratory frame of reference relative to the plasma motion.

Consider, then, the electric field $\boldsymbol{E}_\parallel$ in the direction of $\boldsymbol{B}$. In the presence of strong unequal electron and ion thermal anisotropies, $\boldsymbol{E}_\parallel$ prevents any significant separation of ions and electrons along the field, so that potential differences as large as the thermal energy are theoretically possible. However, in the large-scale slowly evolving plasma there is generally little or no anisotropy, as a consequence of the small-scale plasma instabilities driven by any anisotropy. Therefore, generally $\boldsymbol{E}_\parallel$ can be neglected, with the result that $\boldsymbol{E} = -\boldsymbol{u}\times\boldsymbol{B}/c$ and the Faraday induction equation becomes the familiar MHD induction equation

$$\frac{\partial \boldsymbol{B}}{\partial t} = \boldsymbol{\nabla}\times(\boldsymbol{u}\times\boldsymbol{B})$$

stating that the magnetic field is carried bodily with the bulk motion $\boldsymbol{u}$ of the plasma in the frame of reference in which there is no electric field.

On the other hand, in the presence of small scales and transient conditions, arising in shock fronts, flare current sheets, auroral filaments and sheets, and in the terrestrial magnetopause, there may be substantial $\boldsymbol{E}_\parallel$, with interesting and important dissipation and diffusion not found in the large-scale plasma and field.

Particle drifts

Returning to the guiding center approximation to investigate the individual particle motion, note that the magnetic field $\boldsymbol{B}$ is assumed to vary over the large scale L. The direction of the field may vary along the field, so that the thermal motion $w_\parallel$ of the guiding center along the field introduces a centrifugal force $F = Mw_\parallel^2 K$, where K is the curvature of the field line through the guiding center. The result is the *curvature drift*

$$\boldsymbol{u}_\mathrm{c} = \frac{Mw_\parallel^2 c}{qB^4}\boldsymbol{B}\times[(\boldsymbol{B}\cdot\boldsymbol{\nabla})\boldsymbol{B}].$$

Then the magnitude of the field may vary in a direction perpendicular to the field, so that the cyclotron motion experiences a stronger field on one side of the circle than the other, producing the *gradient drift*

$$\boldsymbol{u}_\mathrm{g} = \frac{Mw_\perp^2 c}{2qB^4}\boldsymbol{B}\times\boldsymbol{\nabla}\frac{B^2}{2}.$$

The bulk acceleration $\mathrm{d}\boldsymbol{u}/\mathrm{d}t$ provides an inertial force $\boldsymbol{F} = M\,\mathrm{d}\boldsymbol{u}/\mathrm{d}t$, producing the *polarization drift*

$$\boldsymbol{u}_\mathrm{p} = \frac{Mc}{qB^2}\boldsymbol{B}\times\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}.$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Note that u_c and u_g are small $O(R/L)$, and u_p is small $O(R/L)(u^2/w^2)$ compared with w, so that in the limit of small R/L the bulk motion reduces to $\boldsymbol{u}$.

Now all three of these drift motions depend on the sign of the charge q. Hence they provide an electric current, with density

$$\boldsymbol{j}_\perp = \frac{c}{B^2}\boldsymbol{B}\times\left[\boldsymbol{\nabla} p_\perp + (\boldsymbol{B}\cdot\boldsymbol{\nabla})\boldsymbol{B}\frac{p_\parallel - p_\perp}{B^2} + \rho\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}\right]$$

on taking into account the several geometrical factors.

The obvious question is whether $\boldsymbol{j}_\perp$ satisfies Ampère's law. Noting that $(\boldsymbol{\nabla}\times\boldsymbol{B})_\perp$ can be written as $\boldsymbol{B}\times[(\boldsymbol{\nabla}\times\boldsymbol{B})\times\boldsymbol{B}]/B^2$, Ampère's law becomes

$$\boldsymbol{B}\times\left[\rho\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}+\boldsymbol{\nabla}_\perp p_\perp+(\boldsymbol{B}\cdot\boldsymbol{\nabla})\frac{p_\parallel - p_\perp}{B^2} - \frac{(\boldsymbol{\nabla}\times\boldsymbol{B})\times\boldsymbol{B}}{4\pi}\right]=0$$

requiring that

$$\rho\frac{\mathrm{d}\boldsymbol{u}_\perp}{\mathrm{d}t} = -\boldsymbol{\nabla}_\perp\left(p_\perp+\frac{B^2}{8\pi}\right)+[(\boldsymbol{B}\cdot\boldsymbol{\nabla})\boldsymbol{B}]_\perp\left(\frac{1}{4\pi}-\frac{p_\parallel - p_\perp}{B^2}\right)$$

for any acceleration perpendicular to $\boldsymbol{B}$. This expression is recognizable as Newton's equation for the bulk motion $\boldsymbol{u}$ perpendicular to the magnetic field $\boldsymbol{B}$. The term $(p_\parallel - p_\perp)/B^2$ represents the net centrifugal force of the excess field-aligned particle motion along the curved lines of $\boldsymbol{B}$. In the common case of near thermal isotropy it can be neglected, and the momentum equations take the same form as with a classical fluid. The essential point is that Ampère's law is automatically satisfied by a plasma (Parker 1957).

The special case of bulk motion $u_\parallel$ parallel to a stationary $(\partial/\partial t = 0)$ field $\boldsymbol{B}$ is described by the equation

$$\rho\left(\frac{\partial}{\partial t}+u_\parallel\frac{\partial}{\partial s}\right)u_\parallel = -\frac{\partial p_\parallel}{\partial s}+\frac{p_\parallel - p_\perp}{B}\frac{\partial B}{\partial s}.$$

where the term in the anisotropy $p_\parallel - p_\perp$ is a consequence of the net diamagnetic moment μ of each particle and the convergence of the field lines. The equation for conservation of particles is

$$\frac{\partial\rho}{\partial t}+\frac{\partial\rho u_\parallel}{\partial s} = \frac{\rho}{B}u_\parallel\frac{\partial B}{\partial s}.$$

The electric current $\boldsymbol{j}_\parallel$ required by the torsion $(\boldsymbol{\nabla}\times\boldsymbol{B})_\parallel$ arises from a weak $\boldsymbol{E}_\parallel$ acting on the particles moving along $\boldsymbol{B}$, particularly those for which $w_\parallel > w_\perp$.

General considerations

These calculations show the mutual consistency of the equations of Newton and Maxwell, established long ago by Poynting's theorems. The MHD equations are the expression of Newton and Maxwell for the large-scale bulk motion of both dense and tenuous plasmas. The MHD induction equation applies to any fluid that cannot support an electric field $\boldsymbol{E}'$ in its own frame of reference. No other assumption is involved. Then note that at each point in space the mechanical gyrations of the electrons and ions in the inhomogeneous magnetic field automatically supply the $\boldsymbol{j}_\perp$ required by Ampère's law. Thus the electric current is a local phenomenon and does not form an electric circuit, in which an emf at any one location affects the current everywhere around the circuit. Each local region creates its own current in exact conformity to Ampère's law and is uninfluenced, except through the eventual consequences of the momentum equation, by what is happening elsewhere around the current path. Thus the large-scale bulk motion of a plasma is a dynamical contest between the inertia and pressure gradients of the plasma and the Maxwell stresses in the magnetic field carried with the plasma.

The electric current is a passive quantity, locally defined, and contains negligible energy and stress. The kinetic energy of the electron conduction velocity is small $O(c^2/L^2\omega_p^2)$ compared with the magnetic free energy associated with the electric current, where ω_p is the electron plasma frequency. Electron inertia comes into the picture only in rapid variations and in intense current sheets in fields with small scales. The MHD equations can be written in terms of $\boldsymbol{j}$ and $\boldsymbol{E}$, of course, by replacing $\boldsymbol{u}$ with the electric drift velocity $c\boldsymbol{E}\times\boldsymbol{B}/B^2$ and expressing $\boldsymbol{B}$ in terms of $\boldsymbol{j}$ through the Biot–Savart integral. The result is a largely intractable global integro-differential equation because of the physical remoteness of $\boldsymbol{j}$ and $\boldsymbol{E}$ from the primary variables $\boldsymbol{u}$ and $\boldsymbol{B}$.

Note that the divergence of the Poynting vector $c\boldsymbol{E}\times\boldsymbol{B}/4\pi$ can be written as $-(\partial/\partial t)B^2/8\pi - \boldsymbol{u}\cdot\boldsymbol{F}_L$ where $\boldsymbol{F}_L$ is the Lorentz force $(\boldsymbol{\nabla}\times\boldsymbol{B})\times\boldsymbol{B}/4\pi$. Expressed in terms of $\boldsymbol{u}$ the Poynting vector can be written $\boldsymbol{u}_\perp B^2/4\pi$, representing the convective transport of magnetic enthalpy $B^2/4\pi$. Thus we can write the energy equation

$$\frac{\partial}{\partial t}\left(\frac{B^2}{8\pi}\right)+\boldsymbol{\nabla}\cdot\left(\boldsymbol{u}_\perp\frac{B^2}{4\pi}\right)+\boldsymbol{u}\cdot\boldsymbol{F}_L = 0.$$

Now if Coulomb interactions (collisions) between particles are introduced, there is a frictional drag between the electron and ion motions, opposing their relative motion required by Ampère's law, and leading to a small electric field $\delta\boldsymbol{E}'$ in the frame of reference of the plasma. The bulk motion of the plasma is not affected by $\delta\boldsymbol{E}'$ because $\delta\boldsymbol{E}'$ exerts no average force on the particles, its effect being cancelled by the frictional drag that requires its introduction. However, $-c\,\boldsymbol{\nabla}\times\delta\boldsymbol{E}'$ must be added to the right-hand side of the induction equation where it appears as a diffusion term, allowing the field to spread out slowly relative to the bulk flow $\boldsymbol{u}$. Resistive diffusion is treated in the article MAGNETOHYDRODYNAMICS and is often negligible in large-scale flows.

There remains the problem of determining the pressure of the dynamical plasma. In the simple case that the thermal motions are approximately isotropic the pressure may vary adiabatically, $\mathrm{d}(p/\rho^\gamma)/\mathrm{d}t = 0$, unless there is significant RADIATIVE TRANSFER or strong thermal conduction. In that case a suitable energy equation must

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

be used to determine the varying temperature of the gas. The polytropic variation $\mathrm{d}(p/\rho^{\alpha})/\mathrm{d}t = 0$ is a device that is sometimes used to represent the pressure–density relation through monotonic compression or expansion, with the parameter α chosen to approximate the actual net heating or cooling.

If the variations of the anisotropic plasma are adiabatic, the Chew–Goldberger–Low approximation may be useful. It is based on the transverse invariant $\mu = Mw_{\perp}^2/2B$ and the longitudinal invariant $\Lambda = hw_{\parallel}$ where h represents the varying scale of the field in the direction of the field as a consequence of longitudinal compression. Conservation of magnetic flux in a flux bundle with cross section S requires that SB be constant, while conservation of particles in the tube requires that $Sh\rho$ be constant. Relating $p_{\perp}$ to μ and $p_{\parallel}$ to Λ, it follows that

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{p_{\perp}}{\rho B}\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{p_{\parallel}B^5}{p_{\perp}^3}\right) = 0$$

There are, of course, more complicated situations where a complete simultaneous solution with the Boltzmann equation may be required.

Finally, there are substantial regions of planetary ionospheres, stellar photospheres and cold dense interstellar gas clouds in which the gas is only slightly ionized, leaving a massive background of neutral atoms that is collisionally coupled to the ions and electrons. This does not alter the basic dynamical principles outlined above, but the dissipation terms become more complicated. The Hall and Pedersen effects are introduced. The ions and electrons collide mainly with neutral atoms rather than with each other. If there are few enough ions and electrons, the Lorentz force of the field, exerted on the ions and electrons, may drive the ions and electrons through the neutral atoms fairly rapidly, representing the Pedersen effect and sometimes referred to as *ambipolar diffusion*. The non-dissipative Hall effect in the large-scale bulk motion is large compared with the resistive diffusion to the degree that the mean free path of the electrons exceeds their cyclotron radius. The Pedersen effect exceeds the Hall effect to the degree that the mean free path of the ions exceeds their cyclotron radius.

Larmor, Joseph (1857–1942)

Physicist, born in Magheragall, County Antrim, Ireland, became Lucasian professor in Cambridge, working on electricity, dynamics and thermodynamics, and especially the ether, the postulated material which pervades space and in which electromagnetic radiation travels. Finding no evidence that the ether existed, he was led to some of the results inherent in EINSTEIN's theory of relativity, giving an explanation of the FITZGERALD contraction independently of LORENTZ. He calculated the energy radiating from an accelerating electron and the splitting of spectral lines in a magnetic field. Larmor's name is used in connection with *Larmor precession*, the spinning of an electron in a strong magnetic field, with the electron said to oscillate at the *Larmor frequency*. Poised at the divide between Newtonian and Einsteinian physics, he could not quite bring himself to believe in relativity.

Las Campanas Observatory

One of the large observatories in Chile, Las Campanas Observatory, is located at the southern edge of the Atacama Desert. The local conditions make Las Campanas an ideal site for optical and infrared observations. Las Campanas is the main observational facility of the CARNEGIE OBSERVATORIES and has been active since 1971. Funding for the operation of Las Campanas is provided by The Carnegie Institution of Washington, a private not-for-profit organization.

Currently functioning telescopes include the 2.5 m du Pont and the 1 m Swope telescopes, while the 6.5 m telescopes of the Magellan Project are currently under construction. The first of these two technologically new instruments will go into operation in early 2000, while the second telescope will go into operation in 2002. The Magellan Project is a joint enterprise with Harvard University, MIT, University of Michigan and University of Arizona. The Universities of Warsaw (Poland), Nagoya (Japan) and Birmingham (UK) operate other telescopes at Las Campanas.

Various imaging, photometric and spectroscopic instruments are available at Las Campanas and a suite of new generation instruments are being built by the partners, for the Magellan telescopes.

Among many fundamental contributions, observations at Las Campanas have provided insight to problems like the Great Attractor, the Las Campanas redshift survey, the universe at high redshift, the age and distance scale of the universe, the structure and chemical composition of our own galaxy, the Galactic Bulge, etc. The supernova 1987A was discovered on a photographic plate obtained at Las Campanas.

Lassell, William (1799–1880)

Born in Bolton, England. A wealthy businessman (a Liverpool brewer), Lassell built progressively larger reflecting telescopes. His innovation was to have them made not in the Herschelian tradition of wood and altazimuthally mounted but with massive, strong iron frames, equatorially mounted on high-quality bearings. He commissioned engineer/astronomer JAMES NASMYTH, to make his 24 in telescope, with a fine machine-figured 500 lb speculum mirror. According to family tradition, Lassell missed using the telescope, erected at his house 'Starfield', to discover Neptune, a letter communicating ADAMS' predicted position having been accidentally destroyed by a too zealous maid. When the coordinates of 'Leverrier's planet', discovered 23 September 1864, were published in *The Times* Lassell found it and saw that not only did Neptune reveal a distinct disc, but it had a satellite, Triton. Lassell also thought it had a ring, like Saturn, but this turned out to be a feature of a maladjusted mirror support system. Lassell went on to discover two moons around Uranus (Ariel and Umbriel) and co-discovered with BOND the eighth moon of Saturn (Hyperion). He moved his 24 in telescope to the clear skies of Malta and built his 48 in telescope there, making a particularly fine study of the Orion nebula. The success of this instrument inspired later generations of astronomers to travel to prime locations (like La Palma and Hawaii) to set up their observatories. The 24 in telescope is being reconstructed in Liverpool.

LDEF (Long Duration Exposure Facility)

Large NASA satellite deployed from the Space Shuttle on 7 April 1984. Intended to expose materials and experiments to open space for one year. Recovery was delayed by the Challenger disaster until 11 January 1989. Carried 57 science and technology experiments to measure the effects of atomic oxygen, space radiation, micrometeoroids, man-made debris, vacuum and other space-related phenomena on more than 10 000 test specimens. Flew in a gravity-gradient stabilized orbit, which gave unique information on the nature and direction of approach of cosmic debris. One meteoroid experiment recorded the direction and precise time of occurrence of more than 15 000 impacts. Also the first satellite to detect beta meteoroids—minute particles accelerated by solar radiation. Impacts on LDEF's trailing edge showed for the first time that debris particles exist in elliptical orbits.

Le Fevre [Le Fèvre; LeFebvre], Jean (1652–1706)

Born in Lisieux, France, became an associate of JEAN PICARD and PHILIPPE DE LA HIRE, became a member of the Académie des Sciences and worked on rather routine work calculating ephemeredes, and surveying. Le Fevre accused La Hire of stealing his tables after Philippe de La Hire published *Tabulae Astronomicae* in 1687. In 1701, resentful at not having been named official publisher of ephemerides to the Académie, Le Fevre published a preface to *Connaissances des Temps* attacking Philippe's son, GABRIEL-PHILIPPE DE LA HIRE. The preface was replaced on government orders and Pontchartrain, La Hire's protector, led a campaign that resulted in Le Fevre being expelled from the Académie.

Leavitt, Henrietta Swan (1868–1921)

Astronomer, born in Lancaster, MA. Became a volunteer and then staff member of the Harvard College Observatory. Directed by PICKERING to work on variable stars in the Magellanic Clouds, measuring their brightness on repeated exposures on photographic plates. Set up standards of photographic magnitudes (brightness) of stars that were accepted worldwide under the name of the 'Harvard Standard', and could be used as comparisons to measure the magnitudes of other stars. Discovered the relation between the period and luminosity of classical Cepheid variable stars. This period–luminosity (P–L) relation made possible measurements of the distances of clusters and galaxies from the Earth and thus the scale of the universe. Leavitt's P–L relation was re-calibrated and used by the Hubble Space Telescope to determine the Hubble constant.

Legendre, Adrien-Marie (1752–1833)

Mathematician, born in Paris (or Toulouse), France, into a rich family. Studied mathematics, and carried out independent research studying the gravitational attraction of ellipsoidal masses (by which could be modeled rotating planets or stars), during which he introduced what are now known as *Legendre functions*. This work brought him membership of the Académie des Sciences. He continued research on celestial mechanics and mathematics, and worked on a triangulation survey between the Paris and Greenwich observatories to measure the Earth. He was a member of the committee of the Académie des Sciences to standardize weights and measures. He lost his wealth in the Revolution in 1793, but nevertheless, with the support of his new wife, he continued scientific work. He published a book describing how to determine the orbit of a comet, under simplifying assumptions, and giving the least squares method of fitting a curve to the data. GAUSS reinvented the least squares method in 1809, acknowledging that it had appeared in Legendre's book, but still claiming priority, something which Legendre found hard to forgive. He made a political blunder in 1824 by not supporting the government's candidate in an election, lost his pension and died in poverty.

Leiden Observatory

The Leiden Observatory (Sterrewacht Leiden) was founded in 1633 and is the oldest university astronomy department in the world. It is part of the Faculty of Mathematics and Natural Sciences of Leiden University.

The research program at Leiden concentrates on the formation and evolution of stars and galaxies. This research makes use of international optical, infrared submillimeter and radio telescopes, as well as theoretical analysis and interdisciplinary laboratory experiments. The goal of the educational program is to train students as independent researchers and problem solvers for careers both as professional astronomers and as leaders of industry. The educational program is broad and accessible to English and/or Dutch speaking students.

Leiden Observatory is an internationally oriented institute, having diverse collaborations with astronomers in Europe, the USA and elsewhere. The institute is a member of the European Association for Research in Astronomy (EARA), a network of top institutes in Cambridge, UK, Paris, Munich and Tenerife, and of the Netherlands Research School for Astronomy (NOVA). It hosts the Sackler Laboratory for Astrophysics and the NOVA-ESO Expertise Center for VLTI (a center for optical interferometry).

During the twentieth century Leiden Observatory has been associated with and produced many outstanding astronomers, including Willem De Sitter, Ejnar Hertzsprung, Jan Hendrik Oort and Hendrik van de Hulst. Leiden Observatory was the cradle of Dutch radio astronomy, where the Dwingeloo and Westerbork radio telescopes were designed and developed. In 1944 van de Hulst predicted that galactic neutral hydrogen should radiate an observable spectral line at 21 cm in the radio. Subsequently 21 cm observations became a fundamental tool in galactic and extragalactic research. The Netherlands Foundation for Radio Astronomy was founded in Leiden by Jan Oort and was located at Leiden Observatory until 1974, when it was moved to Dwingeloo.

At present Leiden Observatory has a permanent scientific staff of seventeen, four technical support staff and two administrative support staff. In addition, there are about eleven post-doctorate positions, thirty-two PhD candidates and fifty undergraduate students.

Lemaître, Abbé Georges Edouard (1894–1966)

Priest, civil engineer and astrophysicist, born in Charleroi, Belgium, became professor of the theory of relativity at Louvain, researched on cosmic rays and the three-body problem. Proposed (1927) independently of FRIEDMANN, an evolving cosmological model in general relativity. This mathematical solution to the EINSTEIN equations, sought but not discovered by Einstein, indicated that the universe had begun in a 'Big Bang', and originated from a dense mass concentration which Lemaître envisaged as a primeval atom. HUBBLE's discovery of the expansion of the galaxies immediately gave credibility to this theory of the origin of the universe.

Lenticular Galaxy

A lens-shaped galaxy that has a central bulge and disk but no spiral arms. Lenticular galaxies, which are denoted by 'S0' or 'SB0' in the Hubble classification scheme, appear to be intermediate in type between elliptical and spiral galaxies. They are flatter than the flattest ellipticals ('E7' ellipticals) but show no signs of spiral structure in their disks. It is possible that they may be spiral galaxies that have been stripped of their gas and dust.

Leo

(the Lion; abbrev. Leo, gen. Leonis; area 947 sq. deg.) A northern zodiacal constellation which lies between Cancer and Virgo, and culminates at midnight in early March. It represents the Nemean lion that, in Greek mythology, Hercules killed as the first of his 12 labors. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large, conspicuous constellation, Leo is easily recognized by the asterism of the Sickle, a back-to-front question mark formed by six of its brightest stars. At the base of the Sickle is α Leonis (Regulus), magnitude 1.4. The next brightest stars in the constellation are β Leonis (Denebola), magnitude 2.1, γ Leonis (Algieba), a binary with orange (K1) and yellow (G7) components, magnitudes 2.5 and 3.6, separation 4.6″, period about 600 years, and δ Leonis (Zosma), magnitude 2.6. There are eight other stars of magnitude 4.0 or brighter. Other interesting stars include R Leonis, a Mira-type variable (range 4.4–11.3, period about 310 days), X Leonis, a U Geminorum star (range 11.1–15.7, mean period about 16.9 days), and Wolf 359 (CN Leonis—a UV Ceti star, range 11.5–17.1), which, at a distance of 7.8 light-years, is the third closest star to the Sun.

Other interesting objects in Leo include the ninth-magnitude spiral galaxies M65 (NGC 3623), M66 (NGC 3627), M95 (NGC 3351), M96 (NGC 3368) and M105 (NGC 3379), the first two and latter three of which appear close together in the sky. There are also many fainter galaxies, including the dwarf spheroidal galaxies Leo I (tenth magnitude) and Leo II (twelfth magnitude), which are members of the Local Group.

The Leonid meteor shower appears to radiate from close to γ Leonis.

See also: Leonids, Regulus.

Leo Group

The constellation LEO contains a rich concentration of galaxies, including five Messier objects. The Leo Group is the nearest group of galaxies with both giant ellipticals and spirals, which makes it valuable for tests of the extragalactic distance scale. The region also harbors two remarkable intergalactic features: a long stream of stars and gas that has been pulled from a SPIRAL GALAXY by gravitational tides and an enormous ring of intergalactic gas the origin of which remains a puzzle.

Nomenclature, extent and mass

The distribution of galaxies in Leo reveals a significant enhancement of bright galaxies within the boundaries shown in figure 1. These galaxies also lie within a narrow REDSHIFT range: more than 100 have measured redshifts in the range 500 km $s^{-1} < cz < 1700$ km s^{-1}, while none has a smaller redshift and only two have redshifts up to 1000 km s^{-1} higher. This concentration of galaxies between about 7 and 25 Mpc is usually called the Leo Cloud, which is a combination of the nearer Leo I Cloud (sometimes described as a 'spur' off of the supergalactic plane) and several groups constituting the more distant Leo II Cloud. The Leo I Cloud can be subdivided further into two groups of galaxies usually labeled by their brightest members as the 'M66 Group' and the 'M96 Group' (see MESSIER OBJECTS). The term 'Leo Group' sometimes refers to a combination of the M66 and M96 groups, but in more recent literature it generally refers to the M96 Group alone. The M66 Group is also frequently called the 'Leo Triplet' because of the three bright galaxies at its core.

Since the distances to most galaxies have not been measured with high precision, it is often difficult to determine the physical relationship of galaxies seen close together on the sky. Early group-identification methods had only a small number of redshifts available, so they relied heavily on visual clues such as the angular sizes of the galaxies and of the morphological features within them. These methods yielded the basic breakdown of groups in the region that is described above and which has been confirmed by independent distance measurements as described later.

Redshift information actually confused questions of membership for a period of time because of the problem of separating a galaxy's Hubble expansion redshift from its Doppler shift due to local dynamical motions. For example, percolation and hierarchical group-identification methods search for neighboring galaxies on the basis of their angular and redshift separation, building chains of associations from which groups are identified. These methods become confused by the Leo region's high density of sources because nearer galaxies with a local dynamical velocity directed away from us and more distant galaxies with a velocity toward us can have similar total redshifts.

The distance-determination problem is exacerbated in the Leo region because of its proximity to the VIRGO CLUSTER.

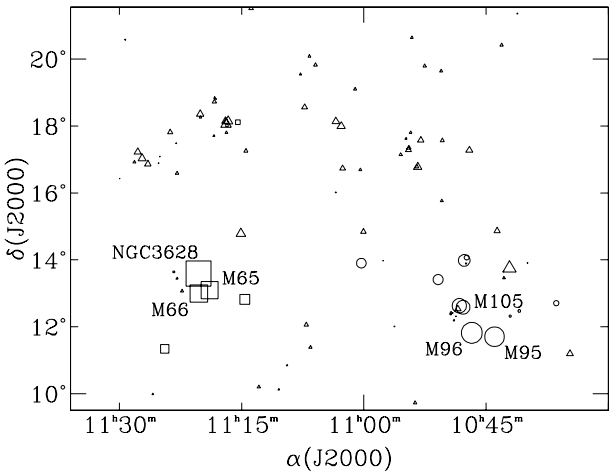

Figure 1. Galaxies in the Leo region with redshifts 500 km $s^{-1} < cz < 1700$ km s^{-1}. Circles indicate likely members of the M96 Group; squares, the M66 Group (Leo Triplet); triangles, members of the background Leo II Cloud. Symbol sizes are proportional to the angular diameter of the galaxy.

While the Leo Cloud is outside of the Virgo Cluster's turnaround radius, the cosmic expansion in the region has been slowed so that the range of redshifts is smaller than would be expected for the depth of the region.

Depending on which galaxies are assumed to be members of a group, estimates of the group mass vary dramatically. Mass-to-light ratios ranging from about $30M_\odot/L_\odot$ to $300M_\odot/L_\odot$ have been claimed for the Leo Group. The highest values result when galaxies from the Leo I and II Clouds are grouped together. However, independent distance measurements indicate that the Leo I and II Clouds are at distinctly different distances. Based on narrower definitions for inclusion in groups, the lower mass-to-light ratios appear more accurate.

Distance laboratory

Independent methods for determining distances are important in extragalactic astronomy because local dynamical motions may make expansion distances inaccurate. Groups of galaxies provide an important testing ground for distance methods, allowing examination of their reliability and accuracy. The Leo Group has been a special focus of distance studies because it includes early- and late-type galaxies and is near enough to permit detailed observations. In addition, M105 (NGC 3379) has been studied heavily as a prototype of surface-brightness distributions within elliptical galaxies, and both M95 and M96 are part of the HUBBLE SPACE TELESCOPE key project on the extragalactic distance scale. M96 even cooperated with the distance studies by producing a type Ia supernova in 1998.

There is a serious difficulty in comparing and cross-calibrating distance methods. Most are applicable to either early- or late-type galaxies, but galaxies tend to separate morphologically, with early-type galaxies residing in dense clusters, and late-type galaxies in the field. Thus the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Table 1. Distances determined for the five major galaxies in the M96 group. The method is labeled in the left-hand column, and the distances in Mpc are listed under each galaxy. The galaxies' morphological types and absolute magnitudes are listed below their NGC and Messier catalog numbers.

Distance technique	M96 NGC 3368 SAB(rs)ab −20.8	M105 NGC 3379 E1 −19.8	M95 NGC 3351 SB(r)b −19.7	NGC 3384 SB(s)0$^-$ −19.2	NGC 3377 E5–6 −18.9
Cepheid variables	11.9 ± 0.8		10.1 ± 0.9		
Type Ia supernovae	10.4 ± 0.8				
SB fluctuations		9.4 ± 0.7		9.5 ± 0.8	9.7 ± 0.8
PN luminosity function	9.6 ± 0.7	10.1 ± 0.7		10.4 ± 0.7	10.6 ± 0.8
Red giant branch tip		11.0 ± 0.7			
Tully–Fisher method	10.2 ± 1.4		9.8 ± 1.4		
Faber–Jackson method		8.7 ± 1.2		9.0 ± 1.7	12.6 ± 2.8

diverse collection of galaxies in the M96 Group provides an unusual opportunity to cross-calibrate distance methods.

The distance of the M96 Group also presents a way for estimating the HUBBLE CONSTANT. Since M105 is a giant elliptical, the same distance method can be used for it as for ellipticals in distant clusters, and an accurate *relative* distance determined. The M96 Group is itself too nearby and its redshift too strongly influenced by the Virgo cluster to provide an accurate expansion/distance ratio directly. Relative distances determined for member elliptical galaxies in the COMA CLUSTER indicate that it is approximately 9.5 times farther away than M105. Thus the M96 Group distance implies a Coma Cluster distance, and the Coma Cluster redshift provides an accurate measure of the expansion. Current estimates of the relative distance of the M96 Group and Coma Cluster indicate that $H_0 \approx 750$ km s$^{-1}/d_{M96}$.

Table 1 lists some of the distance methods that have been applied to the five primary galaxies in the M96 Group. The uncertainties associated with each distance are not all determined by consistent procedures and are probably only indicative of the relative accuracy within that distance method. Overall, the distances indicate that the group is at approximately 10.2 ± 0.2 Mpc based on a weighted average of these measurements.

Cepheid variables permit some of the most accurate distance determinations using the well-calibrated periods and luminosities of Cepheids in the Local Group (see CEPHEID PERIOD–LUMINOSITY RELATION). The value of M96's distance using this method is slightly discrepant with other distance estimates. Since only seven Cepheids were measured in this galaxy and reddening corrections are uncertain, this value may not be as accurate as expected.

The type Ia supernova 1998BU in M96 provides a direct link to another high-accuracy distance standard. Type Ia SUPERNOVAE are important because their peak brightness is an excellent 'standard candle' that can be used over cosmological distances. However, few of these supernovae have been seen in nearby galaxies that have other high-quality distance estimates. One of the difficulties in estimating this type of distance is determining the extinction due to foreground dust. The reddening of this supernova is quite large, producing about 1.66 magnitudes of extinction at B-band. Assuming a peak SN Ia absolute magnitude of $B = -19.38$ yields a distance in excellent agreement with most other methods, although slightly lower than for the Cepheids in M96. It should be noted that different research groups estimate a range of peak SN Ia magnitudes both brighter and fainter than this value.

The surface-brightness (SB) fluctuation technique uses the statistical variation in the number and brightness of stars along different lines of sight through a galaxy to estimate its distance. The values in the table are determined from ground-based observations. Individual observers generally derive consistent results for galaxies within the group, but discrepancies are present between different observers and between ground-based and Hubble Space Telescope determinations. The uncertainties listed in the table partially account for these discrepancies. Recent re-examination of these and other galaxies in the M96 Group indicates that the mean group distance determined using this method is probably closer to 10.7 ± 0.3 Mpc.

The PLANETARY NEBULA (PN) luminosity function uses the observed steep cutoff in PN counts at high luminosities to estimate a distance. The luminosity of the cutoff is effectively a standard candle. The technique has been applied to the early-type galaxies in the group, as well as the bulge of M96, with excellent consistency. Another good luminosity standard has been detected in M105 with the Hubble Space Telescope: stars at the tip of the red giant branch. This provides another independent distance in excellent agreement with the other methods.

Table 1 also lists older results using less accurate methods, which are nonetheless important because of their wide applicability. The TULLY–FISHER method relates spiral galaxies' rotation speed to their luminosity; similarly, the Faber–Jackson method relates the velocity dispersion in early-type galaxies to their luminosity. These values are less accurate, but their overall agreement with the other methods is very good.

The distance to the M96 Group has also been estimated using the globular cluster luminosity function,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Table 2. Other probable members of the M96 Group.

Name	Type	Absolute magnitude
NGC 3489	SAB(s)dm	−18.9
NGC 3412	SB(s)0^0	−18.7
NGC 3299	SAB(s)dm	−16.9
DDO 88	SAB(s)m	−15.9
UGC 5812	Sm	−15.2
CGCG 65–86	dS0	−14.3
Leo dw A	Im	−11.1

applied to a combined sample of globular clusters around both NGC 3377 and NGC 3379, yielding a distance of 10.7 ± 2.2 Mpc. Several other methods have also been applied, using the Leo Group to calibrate the technique, and hence the distances are not independent of the values listed here.

In addition to the five galaxies listed in table 1, several fainter galaxies currently believed to be part of the M96 Group are known at present, including one extremely faint dwarf (Leo dw A) discovered during mapping of hydrogen gas in the group. Table 2 lists these other probable members.

The angular distance between the M66 and M96 Groups indicates they are separated by no less than 1.5 Mpc, so they are probably not part of the same group. Furthermore, the M66 Group is usually estimated to be about 25% closer than the M96 Group based on comparisons of the Tully–Fisher distances; however, tidal disturbances in the Leo Triplet galaxies may degrade the accuracy of these estimates. The distance estimate for the type Ia supernova, SN1989B, in M66 (NGC 3627), suggests the distance may actually be similar to the M96 Group's.

A type Ia supernova (1967C) has also been detected in NGC 3389 in the background Leo II Cloud. This galaxy has a redshift ($cz = 1300$ km s^{-1}) only slightly larger than that of the M96 Group (mean $cz = 950$ km s^{-1}) and is separated by only a few arcminutes from M105 and NGC 3384. The angular and redshift proximities were suggestive that it might be a member of the M96 Group, but the supernova distance is more than 2 times larger than the M96 Group's distance.

Intergalactic features

The Leo I Cloud contains two remarkable intergalactic features. The M96 Group contains intergalactic hydrogen loosely distributed along an elliptical orbit around M105 and NGC 3384, which are near the center of the group (figure 2). This 'ring' of intergalactic gas is about 225 kpc in diameter and contains about $2 \times 10^9 M_\odot$ of neutral hydrogen. Searches for emission at all other wavelengths have been unsuccessful, leaving open the possibility that this gas is primordial.

The ring of gas was discovered in 1983 by chance during 'blank-sky' calibration of observations made of a galaxy in the region. Initial observations uncovered only the denser part of the ring between M105 and M96. This

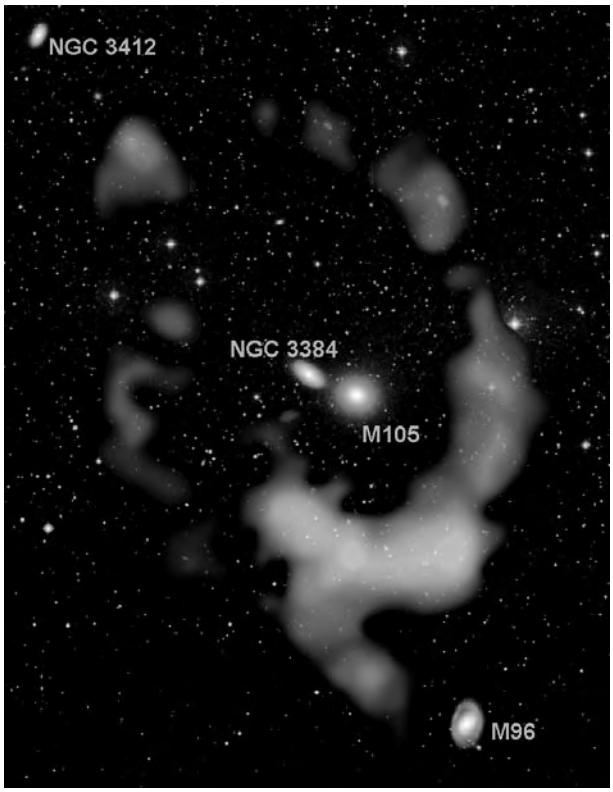

Figure 2. The ring of intergalactic gas in the M96 Group. This is a composite of the optical image from the second Palomar Sky Survey and a gray-scale image depicting the strength of neutral hydrogen emission measured at 21 cm using the Arecibo radio telescope. The intergalactic gas appears to be orbiting the pair of galaxies at the center of the image.

prompted early speculation that the gas might be the result of a Spitzer–Baade collision in which NGC 3384 and M96 collided head-on, stripping NGC 3384 of all of its gas and M96 of a fraction of its gas while the stellar disks passed through each other. Later observations revealed the ring shape of the gas distribution, and the kinematics of the gas indicates it is in an elliptical orbit around the pair of galaxies M105 and NGC 3384.

A spur of gas extends south from the ring toward M96, suggesting a tidal interaction with M96. There is no direct indication from optical or radio observations that the outer portion of M96 is tidally disturbed, so it seems unlikely that the intergalactic gas was stripped from it. Alternatively, the intergalactic gas may come from a disrupted gas-rich dwarf. However, for the gas to become distributed at points all around the ring by differential rotation, several orbits after the initial event would be required. Since the orbital period for the ring is about 4×10^9 yr, this timescale approaches the age of the universe, so it remains plausible that this gas is remnant material from the time of the galaxies' formation.

Another extragalactic feature is found in the M66 Group. In 1956, ZWICKY noted a faint plume of optical

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

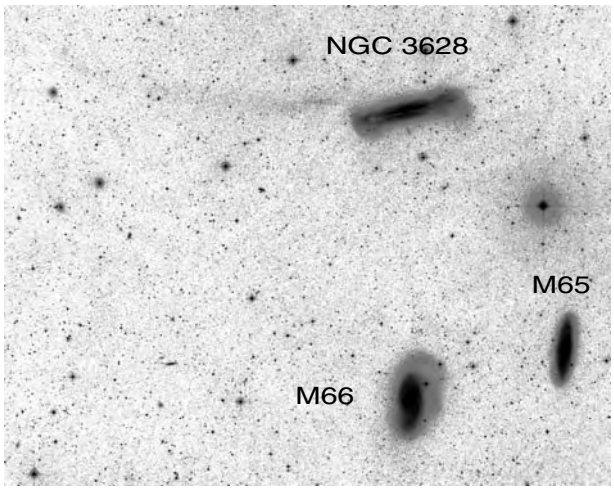

Figure 3. The Leo Triplet of galaxies. Kinematic models indicate that M66 passed by NGC 3628, causing a long tidal plume to be drawn out of NGC 3628. The plume extends east of NGC 3628 almost 100 kpc. This negative of the optical image is from the second Palomar Sky Survey; it is highly 'stretched' to bring out low surface brightness features.

emission outside NGC 3628 (figure 3). At the time, there was considerable interest in the possibility that these features were galaxies in the process of formation. Modern observations and models suggest instead that such features are produced when galaxies suffer close encounters.

The plume extends about 100 kpc east of NGC 3628 and is one of the largest tidal features known. Studies at various wavelengths indicate the presence of stars, gas and dust in similar proportions as would be found in the outer disk of a spiral galaxy. Models indicate that M66 passed close by NGC 3628, and the encounter was in a prograde direction for NGC 3628 but retrograde for M66. As a result, the outer material in NGC 3628 was sped up into much larger orbits while that in M66 became more tightly bound. Both galaxies show morphological indications of disturbance in their outer regions where the low surface brightness emission is distorted. The far end of the plume appears to have a large enough velocity to become unbound from NGC 3628 and may eventually have an appearance similar to a dwarf galaxy.

Bibliography

The groups in the Leo region were originally outlined by

de Vaucouleurs G 1975 Nearby groups of galaxies *Galaxies and the Universe* ed A Sandage *et al* (Chicago, IL: University of Chicago Press) pp 557–600

de Vaucouleurs' divisions have held up remarkably well through the years even though there was relatively little distance or redshift information when the chapter was written in 1965.

The distances of Leo Group galaxies are the subject of intensive research at present. A 1997 paper that reviews many of the techniques employed is

Graham J A *et al* 1997 The Hubble Space Telescope extragalactic distance scale key project. VII. The discovery of Cepheids in the Leo I Group galaxy NGC 3351 *Astrophys. J.* **477** 535

Work on the 1998 supernova in M96 is not yet published, but several new papers re-examining the distance scale in Leo can be expected.

Discoveries about the intergalactic ring of gas in Leo are reviewed by

Schneider S E 1989 Neutral hydrogen in the M96 Group: the galaxies and the intergalactic ring *Astrophys. J.* **343** 94

A popular article from 1984 discusses early investigations of the intergalactic ring and other intergalactic features, including the tidal feature in the Leo Triplet:

1984 Between the galaxies *Am. Sci.* **72** 574

Leo Minor

(the Lesser Lion; abbrev. LMi, gen. Leonis Minoris; area 232 sq.deg.) A northern constellation which lies between Ursa Major and Leo, and culminates at midnight in late February. It was introduced by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* of 1687.

A small, inconspicuous constellation, the brightest stars in Leo Minor are 46 Leonis, magnitude 3.8, and β Leonis, a very close binary with yellow (G8 and F8) components, magnitudes 4.4 and 6.1, separation 0.2″. Interesting objects include NGC 3245, an eleventh-magnitude lenticular galaxy.

Leonardo da Vinci (1452–1519)

Painter, inventor and polymath, born in Vinci (near Empolia), Italy. Although astronomy does not figure large in Leonardo's works, he realized the possibility of constructing a telescope ('making glasses to see the Moon enlarged'). He suggested that '... in order to observe the nature of the planets, open the roof and bring the image of a single planet onto the base of a concave mirror. The image of the planet reflected by the base will show the surface of the planet much magnified'. He understood how the Moon shone by reflected sunlight and he correctly explained the 'old Moon in the new Moon's arms' as reflected light from the Earth.

Leonids

A periodic meteor shower that takes place in November. The radiant lies in the constellation Leo. Some debris from the parent comet, 55P/Tempel–Tuttle, has spread around the orbit to produce a meteor stream that gives modest activity, with an average zenithal hourly rate of 10 in most years. But the greatest concentration of meteoroids remains near the comet. So when the comet returns to perihelion every 33 years there is potential storm activity, particularly if the Earth passes the descending node of the stream's orbit shortly after the comet has. In 1966, for example, some observers estimated that rates were as high as 200 000 per hour in one 40 min period. Not every return of Tempel–Tuttle produces storm activity. Following the great storms of 1799, 1833 and 1866, there was little more than average activity in 1900 and 1933. In 1999 the shower peaked at around 1500 per hour over a 2 h period. The main Leonid swarm (sometimes called the *ortho-Leonids*) is thought to consist of a number of dense ribbons of meteoroids in a sheaf-like configuration. A storm would then occur only if the Earth intersects one of these ribbons. Tempel–Tuttle's retrograde orbit gives the incoming meteoroids a high relative velocity, producing very fast meteors. There are records of Leonid storms going back over a thousand years.

Leptons

Particles that are not acted on by the strong nuclear force and which are not built of quarks. Leptons have no internal structure and cannot be broken down into smaller component particles. The leptons are the electron, the muon, the tau (or tauon), and the three types of neutrino, together with their antiparticles. The muon and tau are negatively charged particles that appear to be heavier analogs of the electron, the mass of the muon (105.6 MeV) being 200 times that of the electron, and the mass of the tau (1.78 GeV) being about 3500 times greater than that of the electron. Neutrinos are particles with zero electrical charge and zero, or exceedingly small, mass. The electron and its associated neutrino (the electron-neutrino), together with two types of quark (the 'up' and 'down' quarks), and their antiparticles, constitute a family of particles called the 'first generation'. The muon and the muon-neutrino form part of the second generation, the tau and tau-neutrino being members of the third generation.

Lepus

(the Hare; abbrev. Lep, gen. Leporis; area 290 sq. deg.) A southern constellation which lies between Orion and Columba, and culminates at midnight in mid-December. It is sometimes said to be the quarry of Canis Major, one of the two dogs of Orion (the Hunter). The brightest stars of Lepus were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small constellation, the brightest stars in Lepus are α Leporis (Arneb), magnitude 2.6, and β Leporis (Nihal), a close binary with a yellow (G5) primary, magnitude 2.8, and a much fainter, magnitude 7.3, companion. There are six other stars brighter than fourth magnitude, including the double star γ Leporis, which has pale yellow (F6) and orange (K2) components, magnitudes 3.6 and 6.2, separation 97″, that share the same common proper motion and radial velocity. Other interesting objects include R Leporis, a Mira-type variable star (range 5.5–11.7, period about 427 days), sometimes called 'Hind's crimson star' after the British astronomer John Russell Hind (1823–95), who remarked on its deep red color, NGC 2017, a small group of six associated stars (magnitude 6.4–12.4), two of which are binaries, IC 418, a ninth-magnitude planetary nebula, and M79 (NGC 1904), an eighth-magnitude globular cluster.

Lescarbault, Edmond

French country doctor living in Orgenes. Claimed that on 26 March 1859 he had watched for an hour the passage of something across the solar disc that matched URBAIN LEVERRIER's calculations for the hypothetical planet Vulcan. Leverrier, co-predictor with ADAMS of Neptune from the deviations of Uranus from its orbit, tried to repeat his earlier success by attributing deviations of Mercury from its orbit to an intra-Mercurial planet, Vulcan, or more than one planet. MAX WOLF had found photographs of a number of circular spots on the Sun, which could also be interpreted as isolated observations of solar transits of a planet inside the orbit of the Earth. LEVERRIER investigated Lescarbault's claims and was shown some figures recorded on prescription paper, covered with grease and laudanum. Surprisingly, he accepted the observations and assimilated them into an orbit of Vulcan. He mobilized French astronomers into a search for Vulcan during the solar eclipse of 1860—no intra-Mercurial planets were found. Other round spots on the Sun were independently photographed at Greenwich and Madrid, at about the time of a possible transit of Vulcan, but when Leverrier predicted that there would be a transit of Vulcan across the Sun on 22 March 1877 nothing was seen. J C Watson and Lewis Swift (1820–1913) claimed to see small planets (at different positions) near the Sun during the total solar eclipse of 1878 but at the 1929 eclipse ERWIN FREUNDLICH found nothing. In 1916, ALBERT EINSTEIN published his general theory of relativity, which explained the deviations in the motions of Mercury as a non-Newtonian effect called the advancement of perihelion, and the need for Vulcan disappeared. The reported sightings were misidentified sunspots (Wolf, Weber), misidentified stars (Watson and Swift) and accidental sightings of small asteroids or Sun-grazing comets passing inside Earth's orbit (Lescarbault).

Leucippus ($fl.$ fifth century BC)

Philosopher, born in Miletus, Asia Minor. Virtually nothing is known of his life, except that he was the founder of Atomism, developed by his disciple DEMOCRITUS and accessibly presented by LUCRETIUS in *De Rerum Natura*. Essentially Atomism is a theory to explain change. Atoms are microscopic particles and are permanent. They move in the permanent framework of space and alter their arrangements—appearances change. It is a recognizably scientific theory. Leucippus is credited with two books, *The Great World System* and *On the Mind*, but his theories and writings are not reliably separable from those of Democritus.

Leuschner, Armin Otto (1868–1953)

Astronomer and teacher, born in Detroit, grew up in Germany, and returned to the USA to lead the astronomy department of the University of California at Berkeley. His research was in celestial mechanics and he calculated orbits of asteroids and comets, developing a technique that succeeded even when based on observations of a rapidly moving Earth-grazing object. He was highly regarded as a teacher.

Leverrier [Le Verrier], Urbain Jean Joseph (1811–77)

Celestial mechanician, born in Saint-Lô, France. Worked at the Paris Observatory, under ARAGO. Later became director where his drive for efficiency and for total control over the staff made him unpopular, particularly his diktat that 'One should not read in the papers the names of assistant astronomers who made discoveries, when the credit belongs exclusively to the director under whose orders they work. Young astronomers should of course receive thanks and a medal for each discovery'. Staff unrest was brought to the attention of the government, and Leverrier was removed from the post. He was later reinstated under the authority of a directing council. Leverrier had found fame as a young man when Arago had suggested that he calculate the position of Neptune from irregularities in Uranus's orbit (*see also* ADAMS). Neptune was found at the predicted place by the German astronomer GALLE. Leverrier attempted to repeat his success with Neptune by examining a discrepancy in the motion in the perihelion of Mercury, and attributed this to an intra-Mercurial planet, which he called Vulcan (*see* EDMOND LESCARBAULT).

Levi ben Gerson (1288–1344)

Philosopher, therologian and astronomer, born in Bagnols, Gard, France. Invented Jacob's staff, an instrument to measure the angles between stars. It is a staff with square cross-section, about 1 m long, with perforated cross-pieces which slide along the staff. The end of the staff is held at the eye and the cross-piece slid along until the two ends fit within the two stars being measured. The staff is calibrated and engraved with the tangent of the angle of separation, so that the angle can be read from the position of the cross-piece. Levi observed solar and lunar eclipses in 1337, giving explanations, and made other astronomical observations of the Moon, Sun and planets using a camera obscura. He wrote that the Milky Way shines by the reflected light of the Sun.

Libra

(the Scales; abbrev. Lib, gen. Librae; area 538 sq. deg.) A southern zodiacal constellation which lies between Virgo and Ophiuchus, and culminates at midnight in early May. The brightest stars of Libra were regarded by the ancient Greeks as comprising the constellation Chelae (the Claws—of the Scorpion) and were cataloged as such by Ptolemy (*c.* AD 100–175) in the *Almagest*. The name Libra was introduced by the Romans in the first century BC to reflect the fact that, at that time, the Sun was in Libra at the autumnal equinox, when day and night are of the same length (in balance), though this idea may date back to the Sumerians of 2000 BC. Libra is the only inanimate object among the zodiacal constellations.

A rather inconspicuous constellation, the brightest stars in Libra are β Librae (Zubeneschamali, from the Arabic for 'the northern claw'—of the Scorpion), magnitude 2.6, and α Librae (Zubenelgenubi, 'the southern claw'), a wide double star with bluish-white (A3) and pale yellow (F4) components, magnitudes 2.8 and 5.2, separation 231″, that share the same proper motion, and a third, unseen companion which revolves around the former. There are four other stars brighter than fourth magnitude. Another interesting star is ι Librae, a multiple system consisting of two close binaries separated by 58″, one consisting of two bluish-white (B9) components, magnitudes 5.1 and 5.6, separation 0.1″, period 22.4 years, and a third, unseen companion, the other consisting of two much fainter components, of magnitudes 10.5 and 11.2v, separation 1.9″. Other interesting objects include the Algol-type variable star δ Librae (range 4.9–5.9, period 2.33 days) and NGC 5897, a ninth-magnitude globular cluster.

Libration

An oscillation of a celestial object about some mean position. The term is used most often in connection with the Moon, to describe a number of effects which cause the hemisphere presented to an observer on the Earth to vary slightly as the Moon proceeds around its orbit. Over time, the Moon appears to rock slightly from side to side, and to nod slightly up and down. Although the Moon has synchronous rotation, rotating on its axis in the same time as it takes to orbit the Earth, the different types of libration make it possible for 59% of the Moon's surface to be visible over the course of a period of 30 years or so. The effect of libration is to make surface features near the Moon's limb sometimes extremely foreshortened, sometimes easier to observe.

The main types of libration are those termed *geometric librations*, which arise from the features of the Moon being observed from different angles at different times. The Moon has an elliptical orbit, in which its orbital velocity varies; this, combined with its constant rate of axial rotation, leads to *libration in longitude*. At perigee and apogee, when closest and farthest from the Earth respectively, the Moon presents its average east–west aspect to the Earth, but between these two positions we can see farther round its western or eastern limb. The difference amounts to a wobble of $\pm 7^\circ\, 45'$. *Libration in latitude* arises from the Moon's orbital plane being inclined to the plane of the ecliptic, and to a lesser extent from the slight inclination of the Moon's equator to its orbital plane. For various positions in its orbit we can therefore see more of one or other of the polar regions. This effect amounts to $\pm 5^\circ\, 9'$. A lesser effect is *diurnal libration*, a result of the Earth's rotation changing the observer's position, so that we can see a little more of the eastern or western limb when the Moon is rising or setting. This effect is greatest for an observer on the equator, where it contributes $57'$. As opposed to geometrical libration there is also *physical libration*, a consequence of small variations of the Moon's orbit caused by its slightly irregular shape. Physical libration amounts to just $2'$.

Lick Observatory

Lick Observatory, located on Mount Hamilton 30 km east of San Jose, California, at an elevation of 1280 m, serves astronomers from throughout the University of California system. It is administered by University of California Observatories/Lick Observatory, which has its headquarters on the Santa Cruz campus. This multi-campus research unit also serves as the University of California liaison with the W M KECK OBSERVATORY. UCO/Lick provides the technical facilities and staff to design and fabricate state-of-the-art instrumentation.

Lick has seven major research telescopes. The original observatory building houses the 110-year-old 36 in (0.9 m) refractor, the second largest in the world, as well as a 1 m reflector. Also on the mountain is a 0.5 m twin astrograph and a 0.75 robotic telescope. The largest telescope is the 3 m Shane reflector.

The research undertaken at Lick spans the diverse interests of University of California astronomers. In 1892, using the 36 in refractor, E E Barnard discovered Jupiter's fifth moon, the first found since Galileo. Today, Lick continues that tradition. The Shane reflector, coupled to the Hamilton high-dispersion echelle spectrograph, has become the world's premier planet finder. Other on-going programs include supernova searches, adaptive optics development and inertial proper motions of stars.

Life on Other Worlds

Life on other worlds refers to the existence of life in any form beyond the Earth. The study of life on other worlds, known today as exobiology, bioastronomy or astrobiology, uses the concepts and techniques of modern astronomy, biology and biochemistry to illuminate the origin, evolution and distribution of life in the universe. Recent historical scholarship has shown, however, that long before the birth of modern science, the question was examined in the context of the 'plurality of worlds' tradition dating back to the ancient Greeks. An important finding of this scholarship is that the idea was often elaborated not in haphazard fashion by marginal figures but in the context of the science (or natural philosophy) of its time, by leading thinkers, who framed their ideas as a serious debate over substantive issues.

During the 20th century life on other worlds has become part of the larger concept of cosmic evolution, the theory that the entire universe is evolving, and that its ultimate end products are not merely planets, stars and galaxies, but life, mind and intelligence. The result is a 'biological universe' rather than a purely physical universe. By its very nature an answer to the question of life on other worlds is extremely difficult. However, because it bears so strongly on the problem of humanity's place in the universe, the answer is one of the most sought-after in the history of science. The debate over life on other worlds is therefore a study of science attempting to answer an extremely important question at the limits of its capabilities. This article covers the history of that debate; the current study of life in the universe is covered in the article on EXOBIOLOGY.

The classical plurality of worlds tradition

The question of life on other worlds began with Greek cosmology, was sustained by medieval commentaries on Aristotle and was transformed by the Copernican theory in the 16th century. In its original meaning the term 'world' meant not a planetary world but the entire *kosmos*, the visible universe that the Greek atomists believed to be a result of the chance collision of atoms and that Aristotle theorized was an ordered set of concentric spheres, with the Earth at the center and the sphere of the fixed stars at its outer periphery. In the Greek atomist view, expounded in the 4th and 5th centuries BC by Leucippus, Democritus and Epicurus, an infinite number of worlds (*aperoi kosmoi*) existed completely beyond the human senses. However, such worlds were not beyond human reasoning; because the infinite number of atoms could not all have been used in our finite world, the atomists deduced that other worlds, some of them inhabited, must be created in like manner. This doctrine was eventually spread throughout Europe by the Roman poet LUCRETIUS (ca 99–55 BC), who reiterated that other worlds must exist 'since there is illimitable space in every direction, and since seeds innumerable in number and unfathomable in sum are flying about in many ways driven in everlasting movement'. The concept of infinite worlds was therefore driven by the physical principles of the atomist cosmology.

In the same way, the physical principles of ARISTOTLE (383–322 BC) were diametrically opposed to an infinite number of worlds. In Aristotle's cosmology the Earth was not only the physical center of the nested spheres, it was also the center of motion. According to Aristotle's doctrine of natural motion and place as expressed in his *De caelo* (On the Heavens), everything in the cosmos moved with respect to that single center—the element earth toward Earth, the element fire away from Earth, while air and water assumed intermediate places. If there were more than one world, the elements of earth and fire would have more than one natural place toward which to move, a physical and logical contradiction. Only one world (in the sense of *kosmos*) could exist.

While the treatise of Lucretius was lost until the 15th century, Aristotle's *De caelo* was transmitted to the Latin West in the 12th century. In the context of Christianity the question of a plurality of worlds (*plures mundi*) was the subject of repeated commentary, most notably in connection with the issue of God's omnipotence. The issue for the Scholastic tradition was whether God could create other worlds if he wished. Gradually over the course of the 13th and 14th centuries the answer evolved from the assertion that God could suspend natural law to create other worlds to the affirmation of the possible existence of more than one center of motion, and therefore more than one world. In reality, however, the medieval Scholastics did not believe that God had created a plurality of worlds.

However, it was not the medieval Scholastic tradition that gave birth to the modern discussion of life on other worlds. That distinction belongs to the heliocentric theory of COPERNICUS, which made the Earth a planet and the planets potential Earths. The *De revolutionibus* (1543) altered the meaning of 'world' from cosmos to planet, where each planet was a center of motion and a world of its own. The question was exactly how similar to the Earth were the planets, an issue that could be explored more scientifically with the invention of the telescope and that has been the driving force for much planetary research ever since. Already in the first announcement of his observations with the telescope in *Siderius nuncius* (Sidereal Messenger, 1610), GALILEO noted that the surface of the Moon was 'not unlike the face of the Earth' and that its bright parts might represent land and its darker parts water. In the same year, KEPLER conjectured that one large and particularly circular lunar crater might be an artificial construction of lunar inhabitants. Bishop JOHN WILKINS, in his *Discovery of a World in the Moone* (1638), made a broader case for lunar inhabitants, and began to address the religious implications.

It did not take long for the question of other solar systems to be broached. As early as 1584 the Dominican monk GIORDANO BRUNO had argued for an infinite number of planetary systems in *De l'infinito universo e mondi* (On the Infinite Universe and Worlds). Although an avowed Copernican, Bruno based his reasoning largely

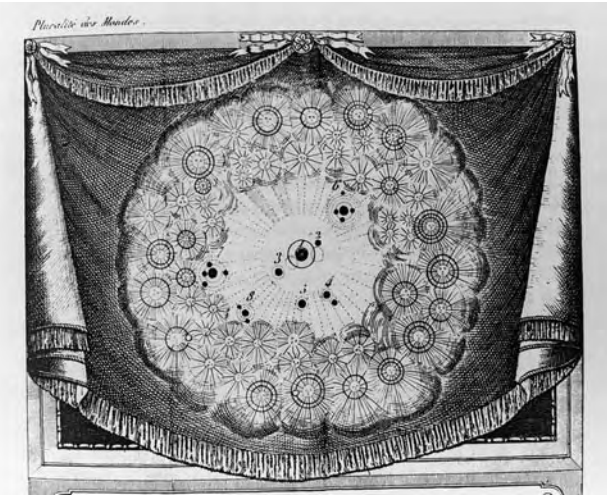

Figure 1. Frontispiece to the 1821 French edition of Fontenelle's *Entretiens sur la pluralité des mondes*, depicting the plurality of solar systems. A similar image adorned the many editions of this work, including the first edition in 1686, graphically spreading the idea of many solar systems.

on metaphysical arguments such as the unity of the universe. His burning at the stake in 1600 by the Roman Inquisition, driven not so much because of his belief in an infinite number of worlds as for his other 'heresies', nevertheless had a chilling effect on those who would speculate on life on other worlds. Thus the French philosopher RENÉ DESCARTES, greatly influenced by a revived atomism, offered in *Principia philosophiae* (Philosophical Principles, 1644) a mechanical philosophy in which a universe full of atoms necessarily formed vortices, systems analagous to our solar system, around every star. Although Descartes himself was careful to avoid speculation about inhabited planets, in his *Entretiens sur la pluralité des mondes* (Conversations on the Plurality of Worlds, 1686) the French Cartesian Bernard le Bovier de Fontenelle spread this idea of a plurality of inhabited solar systems (figure 1). It was also espoused in a similar context in the *Cosmotheoros* (1698) of the Dutch astronomer CHRISTIAAN HUYGENS. Thus it was through the Cartesian cosmology that the idea of other solar systems first became ingrained in European consciousness.

Within 50 years of its inception the Cartesian world view was swept away by the Newtonian system, set forth in NEWTON's *Principia Mathematica* (1687). In the Newtonian world view solar systems did not form by necessity; indeed under Newtonian laws of gravitation the whole question has proved to be one of the greatest complexity until the present day. Although they could not resolve the question of other solar systems by the laws of nature, however, Newtonians were anxious to keep a role for God in the universe, and latched on to the plurality of worlds doctrine as a component of natural theology, arguing that a universe full of life demonstrated the magnificence and omnipotence of God.

During the 18th and 19th centuries little progress was made in characterizing the nature of other planets, and even less in determining whether there might be other solar systems. Much of the discussion may be seen as a struggle of the idea of other worlds with Christianity; although the Newtonians had reconciled other worlds with theism via natural theology, the doctrines of Christianity were another matter. Three choices existed in this struggle: reject other worlds, reject Christianity or reconcile the two. Historically, all three of these possibilities came to pass, as described in detail in Michael Crowe's *The Extraterrestrial Life Debate, 1750–1900* (1986).

The modern tradition: cosmic evolution and life on other worlds

The modern study of life in the universe is intimately connected to the idea of cosmic evolution. Despite the tentative acceptance of Darwin's theory of evolution in the biological realm, at the beginning of the century the universe itself was believed to be static. This was certainly the position of A R Wallace, co-founder with Darwin of the theory of natural selection. His universe, as described in *Man's Place in the Universe: A Study of the Results of Scientific Research in Relation to the Unity or Plurality of Worlds* (1903), was not only static but also only 3600 light years in diameter, with the Earth still situated near the center of the Galaxy. In this view of the universe, shared by many astronomers of the day, Wallace argued that there were no other inhabited worlds and that humanity was the supreme creature. Gradually over the course of the century biological evolution was extended to cosmic evolution (figure 2), whereby the entire universe, some 15 billion light years in extent, existed in a state of constant change ending in abundant life and intelligence. This is one of the most profound changes in world view of the 20th century. The basic tenets (although not the ultimate products) of cosmic evolution have been confirmed by astrophysics, the science whereby the physical nature of celestial bodies may be determined.

The 20th century debate over other worlds focused first on the solar system, specifically the planet Mars. Mars dominated the extraterrestrial life debate for much of the century, progressing from the search for intelligence to searches for vegetation, organic molecules and finally fossils. PERCIVAL LOWELL lauched the first great Martian debate with his claim in 1895 that he had visually detected linear markings on Mars that he interpreted as artificial constructions (canals), built by Martians to channel water on their dying planet. Lowell's Mars was therefore the epitome of planetary evolution. A lengthy debate ensued among astronomers, and not until 1909 did the French astronomer ANTONIADI resolve the 'canals' into dark patches. Not everyone was satisfied even with that evidence, and we know today that very few of the canals have any physical basis. The search for vegetation was the focus from 1924 into the 1960s, based on changes in dark patches on Mars, supported by spectroscopic evidence

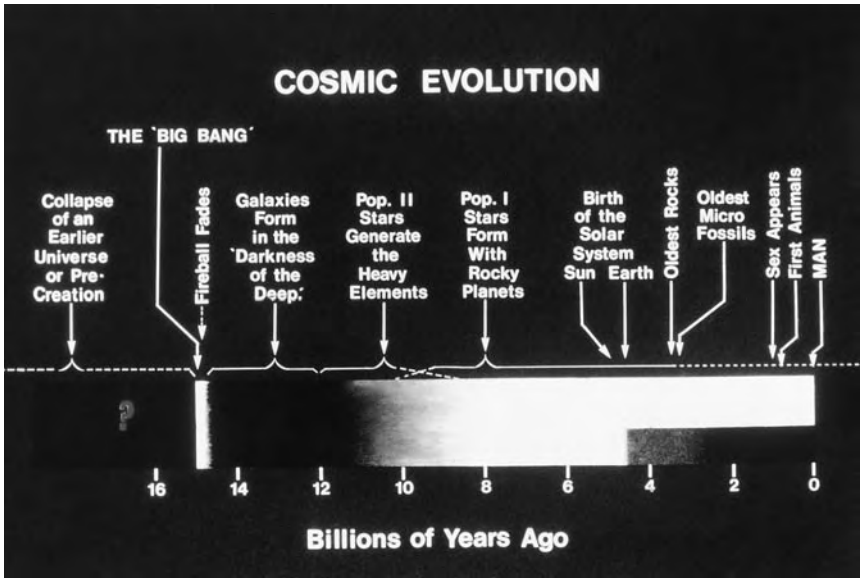

Figure 2. Cosmic evolution, as depicted in this NASA drawing, encompasses events from the Big Bang to intelligence.

in the late 1950s. Such evidence spurred on the space age exploration for life on Mars, culminating with the VIKING landers in 1976. Those landers detected no organic molecules down to parts per billion at the two landing sites. In the wake of this surprising result, the search languished for two decades until the announcement in 1996 of possible fossils in a Martian meteorite found in the Antarctic. Even here, with samples in hand, the evidence was open to interpretation and the sample subject to contamination.

The problem of evidence and interpretation, a constant theme of the 20th century extraterrestrial life debate, is also evident in the search for other solar systems. The 'nebular hypothesis' of Laplace, based on Newtonian gravitation, held that our solar system was formed by condensation from a rotating cloud of gas and dust. If so, solar systems should be a common byproduct of stellar evolution, a process in which the star forms at the center and debris coalesces into planets. This theory was challenged early in the 20th century, first by the Chamberlin–Moulton hypothesis and then the Jeans–Jeffreys hypothesis, both of which had the solar system forming as a result of a very rare encounter between two stars in which material pulled out of the stars formed the planets. However, technical difficulties doomed both theories; by the 1940s a modified nebular hypothesis came into favor, and by the 1950s Harvard astronomer Harlow Shapley could posit the existence of billions of planets. Moreover, the 1940s saw the first observational claims for extrasolar planets, by Kaj Strand and Erik Holmberg, followed by Peter van de Kamp's claims for Barnard's Star in 1963. These observations, based on extremely small gravitational perturbations of the parent star by the supposed planets, were questionable and subsequently proven spurious, and not until 1995 was there confirmation of a planet around a Sun-like star, known as 51 Pegasi. Again, the detection was indirect, using a spectroscopic method to detect the 'Doppler effect' as the star was tugged back and forth by the planet. Since then, more than a dozen planets have been confirmed outside our solar system (see EXOPLANETS). As in the case for Mars, an important lesson is that, despite the difficulties, in the end progress is made.

The existence of planets is only a necessary, not a sufficient, condition for life. Planets must have the right conditions for life to originate, and the origins of life are therefore very important to the question of life on other worlds (see LIFE: ORIGINS AND POSSIBLE DISTRIBUTION IN THE UNIVERSE). It is hampered by our lack of knowledge of how life originated on Earth. During the century three distinct hypotheses have been proposed. Following Darwin's suggestion of life originating in a 'warm little pond', in the 1920s A I Oparin, J B S Haldane and their followers proposed life's origin in a soup of dilute chemicals. The Miller–Urey experiment in 1953, and numerous experiments on prebiotic chemistry under assumed primitive Earth conditions, have been the mainstay of origins of life research during the century. An alternative theory, the panspermia hypothesis, was championed by Arrhenius at the beginning of the century and refined by others at its end. It claimed that life came in some form from outer space, a claim reinforced by the discovery of possible fossil life in the Martian meteorite. At the very end of the century, with the discovery of bacteria existing under extreme conditions of temperature, pressure and acidity, a third theory gained ground: the idea of life originating underground in a 'deep biosphere', and gradually emerging on the surface as conditions

improved. With such new discoveries, the field of origin of life was poised to make good progress in the 21st century, especially with NASA's renewed committment to astrobiology.

The Search for Extraterrestrial Intelligence (SETI) attempted to leapfrog all other arguments by detecting a signal, usually at radio wavelengths, produced by intelligence. Frank Drake undertook the first such search with an 85 foot radio telescope at Green Bank, West Virginia, in 1960. Since then numerous searches have been undertaken with increasingly sophisticated signal detectors, processing millions of channels simultaneously. Even so, most searches have only reached 100 light years and have utilized only a few of the billions of channels possible. The SETI INSTITUTE's Project Phoenix, University of California's Project SERENDIP and Harvard's BETA Project are three of the most important SETI searches now underway.

The theory that life is abundant in the universe is sufficiently comprehensive to qualify as a world view, with the same status as the Copernican and Darwinian world views. The idea of the 'biological universe', or the 'biophysical cosmology', as such a world view places the debate in proper perspective in the history of science. As with other world views, the biological universe bears heavily on humanity's place in the universe, and therefore arouses passionate debate. Like them, it deals with a basic property of the universe and like them it is testable: the Viking landers were local tests of the world view, and SETI is a more far-reaching test. Finally, like other world views the idea of a biological universe has found expression in popular culture, in this case chiefly in the form of debate over unidentified flying objects, and in science fiction, which incorporates the alien as one of its major themes. As the latest subject in the venerable search for our place in the universe, the question of the biological universe shows no signs of abating.

Life: Origins and Possible Distribution in the Universe

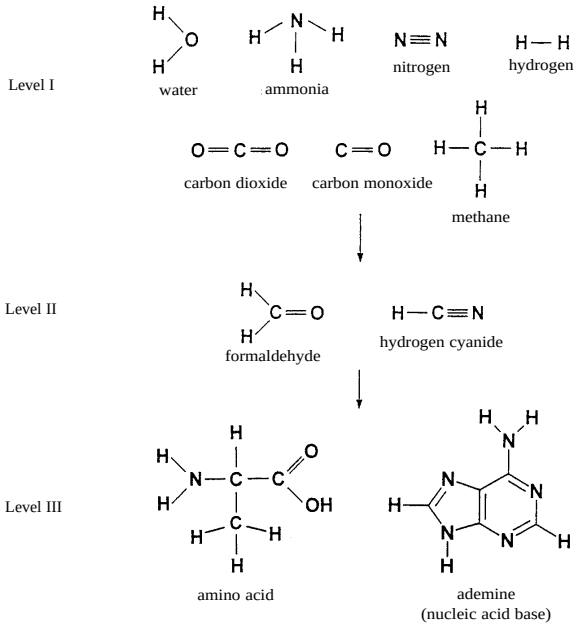
On Earth, life probably originated in liquid water with chemical systems capable of transferring their molecular information via self-replication and also to evolve by mutation. Unfortunately, the direct clues which may help chemists to identify the molecules which participated in the emergence of life on Earth about 4 billion years ago have been erased by plate tectonics, the permanent presence of running water, the unshielded solar ultraviolet radiation and by oxygen produced by life. By analogy with contemporary life, it is generally believed that primitive life originated from the processing by liquid water of reduced organic molecules mainly built of carbon, hydrogen, oxygen and nitrogen atoms. Organic matter might have been formed in the primitive Earth atmosphere or in hydrothermal vents. A large fraction of prebiotic organic molecules might have been brought by extraterrestrial meteoritic and cometary dust grains decelerated by the atmosphere. Any celestial body harbouring permanent liquid water may therefore accumulate the ingredients which generated life on the primitive Earth. The possibility that life might have evolved on early Mars when water existed on the surface marks it as a prime candidate in a search for bacterial life beyond Earth. Europa has an icy carapace. However, cryovolcanic flows at the surface point to a possible water subsurface region which might harbor a basic life form. The atmosphere and surface components of Titan is also of interest to exobiology for the insight into a hydrocarbon-rich living world. One-handed complex molecules and preferential isotopic fractionation of carbon, common to all terrestrial life forms, can be used as basic indicators when searching for life beyond Earth.

Origins of terrestrial life

Water

It is generally thought that life on Earth emerged in liquid water. For this reason, water is considered as one of the prerequisites for life to appear and evolve on a planet. In contemporary living systems, water participates as a solvent in the organization of biopolymers in three-dimensional structures and as a chemical reactant in most of the biochemical pathways. Hydrogen bonds are formed between water molecules and organic molecules providing that the latter contain –OH, –NH, –SH groups in addition to carbon and hydrogen. As a consequence of this affinity many CHONS organic molecules are soluble in water. Hydrocarbons cannot form hydrogen bonds with water molecules and are consequently insoluble in water. Abiotic organic molecules can be divided into two families: hydrocarbons and CHONS-containing molecules. When brought into the presence of liquid water, hydrocarbons try to escape the water molecules while CHONS have some affinity for water, especially those which bear ionizable groups. When these two species are forced to coexist within the same molecules, the duality generates interesting topologies. When they are separated by long distances—such as in fatty acids or phospholipids—micelles, vesicles or liposomes are formed due to clustering of the hydrophobic groups. Over short distances, hydrophobic and ionizable groups generate chain conformations which depend strongly on the sequence i.e. the distribution of the group along the chains.

Water molecules are widespread in the universe as grains of solid ice or as very dilute water vapor. Liquid water is a fleeting substance which can persist only above 0 °C and at pressures higher than 6 mbar. Therefore, the size of a planet and its distance from the star are two basic characteristics that will determine the presence of liquid water. If a planet is too small, like Mercury or the Moon, it will not be able to retain any atmosphere and, therefore, liquid water. If the planet is too close to the star, the mean temperature rises due to starlight intensity. Any sea water present would evaporate delivering large amounts of water vapor to the atmosphere thus contributing to the GREENHOUSE EFFECT. Such a positive feedback loop could lead to a runaway greenhouse: all of the surface water would be transferred to the upper atmosphere where



Scheme 1. The build-up of prebiotic molecules. Simple gaseous molecules like H_2, N_2, H_2O, NH_3, CO, CO_2 (Level I) require a supply of energy (UV, heat, lightning, cosmic rays, shock waves) to react with each other. They generate compounds like hydrogen cyanide and formaldehyde which store chemical energy in their double and triple bonds (Level II). These multiple bonded molecules react spontaneously in liquid water to form prebiotic molecules like amino acids or nucleic acid bases (Level III).

photodissociation by ultraviolet light would break the molecules down into hydrogen, escaping into space, and oxygen combining to the crust. If a planet is far from the star, it may host liquid water providing that it can maintain a constant greenhouse atmosphere. However, water would provoke its own disappearance. The atmospheric greenhouse gas, CO_2 for instance, would be dissolved in the oceans and finally trapped as insoluble carbonates by rock-weathering. This negative feedback would lower the surface pressure and the temperature to an extent where water would be largely frozen. The size of the Earth and its distance from the Sun are such that the planet never experienced either a runaway greenhouse or a divergent glaciation.

Terrestrial production of reduced organic molecules

Oparin suggested that the small reduced organic molecules needed for primitive life were formed in a primitive atmosphere dominated by methane (see scheme 1).

The idea was tested in the laboratory by Miller (1998) when he exposed a mixture of methane, ammonia, hydrogen and water to electric discharges. In his initial experiment, he obtained four of the twenty naturally occuring amino acids (table 1), via the intermediary formation of hydrogen cyanide and formaldehyde. Miller's laboratory synthesis of amino acids occurs efficiently when a reducing gas mixture containing significant amounts of hydrogen is used.

Table 1. Twenty amino acids are used by living systems to build up proteins. Seventeen have been obtained in the laboratory under primitive Earth-simulating conditions (arginine, histidine and lysine are still missing). Eight of them (glycine, alanine, valine, isoleucine, leucine, proline, aspartic acid and glutamic acid) are present in the Murchison meteorite.

However, the true composition of primitive EARTH'S ATMOSPHERE remains difficult to define. The source of the primitive terrestrial atmosphere can be found in a combination of the volatiles CO_2, N_2, H_2O, trapped in the rocks that made the bulk of the planet's mass (internal reservoir) and a late accreting veneer of extraterrestrial material (external reservoir). The formation of the internal reservoir is a natural consequence of the ACCRETION of the planet. A late-accreting veneer of volatile-rich meteorites and comets may have contributed to replace the atmosphere produced by the planet's early accretion, which was subsequently blown off by the giant impact between the Earth and a Mars-sized planetary embryo which generated the Moon and caused the early atmosphere massive hydrodynamic loss. The abundance and isotopic ratios of noble gases neon, argon, krypton and xenon suggest that meteorites alone or in combination with planetary rocks could not have produced the Earth's entire volatile inventory and that a significant contribution from icy PLANETESIMALS was required (Owen 1998).

The discovery of sugar and several related organic compounds in two carbonaceous meteorites (which contain carbon as one of their important constituents) in 2002 suggests another fundamental building block of life on Earth may have come from outer space. Other organic, carbon–based compounds that play major roles in life on Earth, such as amino acids and carboxylic acids, have previously been found in meteorites, but no sugars. Sugars and the closely related compounds recently discovered collectively called polyols, are critical to all known life forms. They act as components of the nucleic acids RNA and DNA, constituents of cell membranes and cellular energy sources. A small sugar called dihydroxyacetone and several sugar–like substances, known as sugar acids and sugar alcohols, have been identified in a study of the Murchison and Murray meteorites. All these are important for life today. One sugar alcohol, glycerol (also known as glycerin), that is used by all contemporary cells to build cell walls has also been found. In addition, preliminary evidence of other compounds that may contain larger sugars critical in cellular metabolism, such as glucose have been discovered.

Water in contact with the olivine of ultramafic rock is reduced to molecular hydrogen (H_2) with the concomitant oxidation of Fe^{II}. The molecular hydrogen formed may be combined at high temperature with CO_2 for the abiotic formation of organic compounds such as hydrocarbons and fatty acids through Fischer–Tropsch type (FTT) synthesis. The analyses of fluids from the peridotite–hosted Rainbow hydrothermal field on the Mid–Atlantic Ridge indicate de novo synthesis of linear saturated hydrocarbons. The chain length of the hydrocarbons is between 16 and 29 carbon atoms. The discovery of FTT reactions in ultramafic hydrothermal systems on Earth provides an alternative pathway for the formation of early membranes and the origin of life.

The surface temperature of the early Earth was very much dependent upon the partial pressure of CO_2 in the atmosphere. The dominant view in recent years has been that the early atmosphere was a weakly reducing mixture of CO_2, N_2, and H_2O, combined with lesser amounts of CO and H_2 (Kasting and Brown 1998). An efficient greenhouse effect induced by a high CO_2 partial pressure was the most likely mechanism capable of compensating for the faint young Sun, the luminosity of which was about 30% lower than today. The dominant sink for atmospheric CO_2 was silicate weathering on land and subsequent formation and deposition of carbonate sediments in the ocean. However, a negative feedback system probably maintained the Earth's surface temperature above freezing: if the temperature were to drop below freezing, silicate weathering would slow down and volcanic CO_2 would accumulate in the atmosphere. The CO_2 partial pressure could have been as high as 10 bar prior to the emergence of the continents because of limited silicate weathering and continental carbonate rocks storage. Under these conditions, the early Earth could have been as hot as 85 °C. Recent analysis of samarium/neodymium ratios in the ancient zircons indicate that the continent grew rapidly, so a dense CO_2 atmosphere may have been restricted to the first few hundred millions of years of the Earth's history.

In a weakly reducing gas mixture of CO_2, N_2, and H_2O, the production of amino acids appears to be very limited. More recently, Wächterhäuser (1998) suggested that the carbon source for life was carbon dioxide. The energy source required to reduce carbon dioxide was provided by the oxidative formation of pyrite (FeS_2) from troilite (FeS) and hydrogen sulfide. Pyrite has positive surface charges and bonds the products of carbon dioxide reduction, giving rise to a two-dimensional reaction system, a surface metabolism. Experimental laboratory work is about to legitimate this new hypothesis.

Deep-sea hydrothermal systems may also represent likely environments for the synthesis of prebiotic organic molecules and perhaps for primitive life (Stetter 1998). Experiments have been carried out in order to test whether amino acids can be formed under conditions simulating the hydrothermal vents (Holm and Andersson 1998).

Extraterrestrial delivery of organic molecules to Earth

COMETS show substantial organic material. According to Delsemme's analysis (1998), Comet Halley dust particles ejected from the nucleus contains 14% organic carbon by mass. About 30% of cometary grains are dominated by light elements C, H, O, N and 35% are close in composition to carbonaceous chondrites. Among the molecules identified in comets are hydrogen cyanide and formaldehyde.

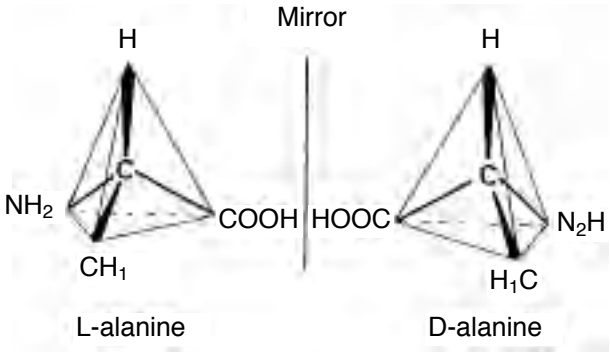

Figure 1. Each amino acid—with the exception of glycine—is asymmetrical and exists under two non-superimposable mirror images called enantiomers L and D. Only L enantiomers are found in proteins.

The presence of purines, pyrimidines and formaldehyde polymers has also been infered from the fragments analyzed by Giotto Picca and Vega Puma mass spectrometers. However, there is no direct identification of the complex organic molecules present in the dust grains and in the cometary nucleus. Many chemical species of interest for exobiology have been detected in Comet Hyakutake in 1996, including ammonia, methane, acetylene (C_2H_2), acetonitrile (CH_3CN) and hydrogen isocyanide (HNC) (Irvine *et al* 1996). In addition to hydrogen cyanide and formaldehyde (H_2CO), seen in several earlier comets, Comet Hale–Bopp was also shown to contain methane, acetylene, formic acid (HCOOH), acetonitrile, hydrogen isocyanide, isocyanic acid (HNCO), cyanoacetylene (HC_3N_2) and thioformaldehyde (H_2CS). Cometary grains might, therefore, have been an important source of organic molecules delivered to the primitive Earth.

The study of METEORITES, particularly the carbonaceous chondrites that contain up to 5% by weight of organic matter, has allowed close examination of extraterrestrial organic material delivered to the Earth. Eight proteinaceous amino acids have been identified in the Murchison meteorite among more than 70 amino acids (Cronin 1998). These amino acids are asymmetric and the two-handedness L and D are generally found in equal proportions.

However, Cronin and Pizzarello recently found excesses of L enantiomers of about 9% for non-protein amino. The presence of L-enantiomeric excesses in the Murchison meteorite suggests an extraterrestrial asymmetric synthesis of amino acids, asymmetry which is preserved inside the meteorite. These excesses may help to understand the emergence of one-handed (homochiral) life. For example, proteins are built up with twenty different amino acids (table 1). Each amino acid, with the exception of glycine, exists in two enantiomeric forms L and D but proteins use only L ones (see figure 1). Proteins adopt asymmetrical rigid geometries, α-helices and β-sheets, which play a key role in the catalytic activity. Homochirality is now believed to be not just a consequence of life, but also a prerequisite for life, because stereoregular structures such as protein β-sheets do not form with mixtures of amino acids of both handedness. The excess of one-handed amino acids found in the Murchison meteorite may result from the processing of the organic mantles of interstellar grains by circularly polarized synchrotron radiation from a neutron star remnant of a supernova. Strong infrared circular polarization resulting from dust scattering in reflection nebulae in the Orion OMC-1 star-formation region has ben recently observed. Circular polarization at shorter wavelengths might have been important in inducing chiral asymmetry in interstellar organic molecules that could be subsequently delivered to the early Earth. Whether the extraterrestrial organic material collected on Earth bear witness to the interstellar organic chemistry is still unknown and we really need to gain more information about the different steps between interstellar medium (ISM)—where more than 100 molecules, the bulk of them organic, have been detected so far by radioastronomers (Irvine 1998)—and the Earth in order to better understand the global ISM–comets–planets ecosystem from an exobiology point of view.

Dust collection, both above the terrestrial atmosphere and in the Greenland and Antarctica ice sheet (Maurette 1998), shows that the Earth captures interplanetary dust as MICROMETEORITES at a rate of about 50–100 tons per day. About 99% of this mass is carried by micrometeorites in the 50–500 μm size range. This value is about 2000 times higher than the most reliable estimate of the meteorite flux, i.e. about 0.03 tons per day. This amazing dominance

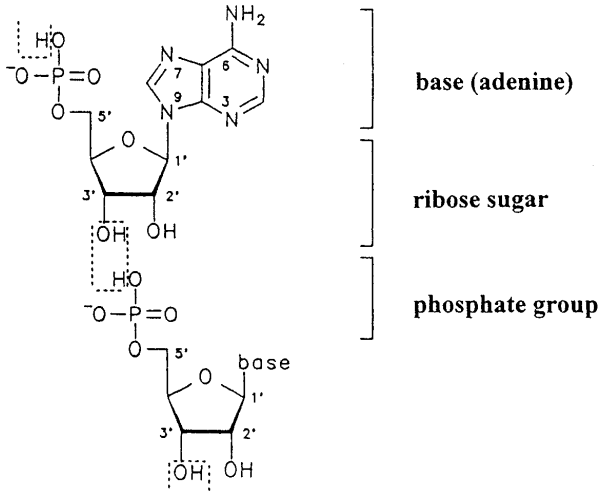

Figure 2. Nucleotides are the building blocks of nucleic acids. Each nucleotide is composed of a phosphate group, four different heterocyclic bases and a ribose sugar. The bases can be reconstructed in the laboratory under primitive Earth-simulating conditions. They are also present in the Murchison meteorites. The spontaneous formation of the ribose sugar is still an unsolved challenge.

of micrometeorites already suggests their possible role in delivering complex organics to the early Earth 4.2–3.9 Gyr ago when the micrometeorite flux was enhanced by a factor of 1000. In the Antarctic micrometeorites, a high percentage of unmelted chondritic micrometeorites from 50 to 100 μm in size has been observed, indicating that a large fraction crossed the terrestrial atmosphere without drastic thermal treatment. In this size range, the carbonaceous micrometeorites represent 80% of the samples and contain 2% of carbon, on average. They might have brought about 10^{20} g of carbon over a period of 300 million years corresponding to the late terrestrial bombardment phase. This delivery represents more carbon than that engaged in the surficial biomass, i.e. about 10^{18} g. Amino acids such as α-amino isobutyric acid have been recently identified in these Antarctic micrometeorites. These grains also contain a high proportion of metallic sulfides, oxides and clay minerals which belong to various classes of catalysts. In addition to the carbonaceous matter, micrometeorites might also have delivered a rich variety of catalysts, having perhaps acquired specific crystallographic properties during their synthesis in the microgravity environment of the early solar nebula. They may have functioned as tiny chondritic chemical reactors when reaching oceanic water.

Primitive cellular life

By analogy with contemporary living systems, it was first generally believed that primitive life emerged as a cell-like organized system thus requiring, at least, boundary molecules able to isolate the system from the aqueous environment (membrane), catalytic molecules providing the basic chemical work of the cell (enzymes) and informative molecules allowing the storage and the transfer of the information needed for replication (RNA).

Boundary molecules

Fatty acids are known to form vesicles when the hydrocarbon chains contain more than ten carbon atoms. Such vesicle-forming fatty acids have been identified in the Murchison meteorite. However, the membranes obtained with these simple amphiphiles are not stable over a broad range of conditions. Stable lipids can be obtained by condensing fatty acids with glycerol or with glycerol phosphate, thus mimicking the sf contemporary phospholipids. Primitive membranes could initially have also been formed by simple isoprene derivatives (Deamer 1998).

Catalytic molecules

Most of the catalytic chemical reactions in a living cell are achieved by proteinaceous enzymes made of 20 different

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

homochiral L-amino acids. Amino acids were most likely available on the primitive Earth as complex mixtures. The number of condensing agents capable to assemble amino acids into peptides in water is restricted, especially when looking for prebiotically plausible compounds. Carbodiimides, R–N=C=N–R, can be used in water providing a careful choice of the substituent R and of experimental conditions. The simplest carbodiimide, H–N=C=N–H, can be considered as a transposed form of cyanamide NH_2–CN which is present in interstellar medium. In water, cyanamide forms a dimer, dicyandiamide, which is as active as carbodiimides to form peptides. However, the reactions are very slow and did not proceed beyond the tetrapeptide. Diaminomaleonitrile, the tetramer of HCN, has been found to form diglycine in 3.1% yield.

Clays and salts can also be used to condense amino acids in water. Amino acid adenylate anhydrides condense readily in the presence of montmorillonite. When subjecting mixtures of glycine and kaolinite to wet–dry and 25 °C–94 °C temperature fluctuations, the formation of oligopeptides up to five glycines long has been observed. The drying/wetting cycle procedure was extended to alanine in the presence of silica, alumina and smectic clays. Mutual catalysis of amino acids in the salt-induced peptide formation reaction has been demonstrated for the case of glycine/alanine. Efficient mineral-catalyzed (hydroxylapatite, illite clay) condensation of amino acids into long peptides have been recently reported (Ferris 1998).

Thermal condensation of amino acids has been described by Fox. He has shown that dry mixtures of amino acids polymerize when heated at 130 °C to give 'proteinoids'. In the presence of polyphosphates, the temperature can be decreased to 60 °C. High molecular weights were obtained when an excess of acidic or basic amino acids are present. In aqueous solutions, the proteinoids aggregate spontaneously in microspheres of 1–2 μm, presenting an interface resembling the lipid bilayers of living cells. The microspheres increase slowly in size from dissolved proteinoids and are sometimes able to bud and to divide. These microspheres are described as catalyzing the decomposition of glucose and work as esterases and peroxydases. The main advantage of proteinoids is their organization into particles but they represent a dramatic increase in complexity. When heating a mixture of selected L-amino acids, the resulting condensate is only 50% peptidic, the peptidic fraction is racemized, the peptide linkages are ambiguous since they include the α, β and γ functions of the dicarboxylic amino acids and the sequences are multiple although not completely random.

According to De Duve, the first peptides appeared via thioesters. Chemical reactions capable to selectively condense the protein amino acids at the expenses of the non-protein ones have been described. Helical and sheet structures can be modeled with the aid of only two different amino acids, one hydrophobic, the second hydrophilic. Polypeptides with alternating hydrophobic and hydrophilic residues adopt a water-soluble β-sheet geometry because of hydrophobic side-chain clustering. Due to the formation of β sheet, alternating sequences gain a good resistance toward chemical degradation. Aggregation of alternating sequences into β sheets is possible only with all-L or all-D polypeptides. When hydrophobic and hydrophilic amino acids coexist within the same polypeptide chain, the duality generates interesting topologies such as stereoselective and thermostable β-sheet structures. Short peptides have also been shown to exhibit catalytic properties (De Duve 1998).

Informative molecules

In contemporary living systems, hereditary memory is stored in nucleic acids built up with bases (purine and pyrimidine), sugars (ribose for RNA, deoxyribose for DNA) and phosphate groups.

The accumulation of significant quantities of natural RNA nucleotides does nor appear as a plausible chemical event on the primitive Earth (Schwartz 1998). Purines are easily obtained from hydrogen cyanide or by submitting reduced gas mixtures to electric discharges. No pyrimidine synthesis from electric discharges has been published so far whereas hydrogen cyanide affords only very small amounts of the base. Condensation of formaldehyde leads to ribose among a large number of other sugars. The synthesis of purine nucleosides (the covalent combination of purine and ribose) and of nucleotides have been achieved by heating the components at the solid state. The yields are very low and the reactions are not regioselective. Interestingly, efficient clay-catalyzed condensation of nucleotides into oligomers up to 55 monomers long have been recently reported (Ferris 1998).

The synthesis of oligonucleotides is much more efficient in the presence of a preformed pyrimidine-rich polynucleotide acting as a template. Non-enzymatic replication has been demonstrated by Orgel and his coworkers. The preformed chains align the nucleotides by base pairing to form helical structures which bring the reacting groups in close vicinity.

The prebiotic synthesis of oligonucleotides remains an unsolved challenge. Each step of the chemical pathway has been achieved in the laboratory but the desired product is never dominant. It is always contaminated with by-products which are wastes or even poisons. Chemists have considered early living systems using simpler informative molecules. The ribose sugar has been replaced by glycerol for the backbone build up. The chemistry of these simplified informative molecules does

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

not appear much easier. The straightforward and selective formation of ribose diphosphates from glycolaldehyde phosphate suggests that pyranosyl–RNA may have been involved in the early forms of life. Intense experimental work is presently run in Eschenmoser's laboratory along this new avenue (Schwartz 1998).

Primitive life only based on RNA?

Cech found that some RNA, the ribozymes, are able to act as catalytic molecules (James and Ellington 1998). For example, they increase the rate of hydrolysis of oligoribonucleotides. They act also as polymerization templates since chains up to 30 monomers long can be obtained starting from a pentanucleotide. Since this primary discovery, the catalytic spectrum of these ribozymes have been considerably enlarged by directed test tube molecular evolution experiments initiated in Joyce's and Szostak's laboratories. Since RNAs have been shown to be able to act simultaneously as informative and catalytic molecules, RNA has been considered as the first living system on the primitive Earth (RNA world) because they can be at the same time genotypes and phenotypes and can fulfill the basic cycle of life consisting of self-replication/mutation/selection. One should, however, remember that their synthesis under prebiotic conditions remains an unsolved challenge. It seems unlikely that life started with RNA molecules because these molecules are not simple enough. The RNA world appears as an episode in the evolution of life before the appearance of cellular microbes rather than as the birth of life. Chemists are now tempted to consider that primitive self-replicating systems must have used simpler informational molecules than biological nucleic acids or their analogs. Since self-replication is, by definition, autocatalysis, they are searching for simple autocatalytic molecules capable of mutation selection. Rebek and co-workers have used nucleic base-like A–B templates able to form hydrogen-bonded ternary complexes with individual A and B subunits and to catalyse the synthesis of new A–B molecules (Burmeister 1998). These experiments are illuminating examples of autocatalysis but they do not yet address the problem of self-replication of long linear sequences. Von Kiedrowski showed that simple A–B molecules unrelated to nucleotides can provide exponentially replicating autocatalytic models. Luisi has demonstrated beautiful examples of autocatalytic micelle growth. However, these autocatalytic systems do not really store hereditary memory and cannot therefore evolve by natural selection.

Geological records of primitive life

The geological record also provides important information. The isotopic signatures of the organic carbon of the Greenland metasediments bring indirect evidence that life may be 3.85 billion years old. Schidlowski has compiled the carbon isotopic composition of over 1600 samples of fossil kerogen (a complex organic macromolecule produced from the debris of biological matter) with carbonates in the same sedimentary rocks. The organic matter has an average $\delta^{13}C$ of $-25\pm7‰$, whereas the carbonate varies by no more than about ‰ around a mean of ‰ ($\delta^{13}C$ expresses the permil deviation of the $^{13}C/^{12}C$ ratio of the sample relative to that of a conventional standard, the carbonate skeleton of a fossil cephalopod which has a $^{13}C/^{12}C$ ratio of 0.0112). The *ca* 25–30% shift is taken as an indication that biosynthesis by photosynthetic organisms was involved. In fact, this offset is now taken to be one of the most powerful indications that life on Earth was active nearly 3.9 Gyr ago because the sample suite encompases specimens right across the geologic timescale. Some organic matter in ancient sediments has been measured as being even more enriched in the light isotope of carbon which would suggest involvement of methane-utilizing organisms. This conclusion is fully consistent with the remarkable diversity of the 3.465 billion year old fossilized microflora (Schopf 1998).

Were the first replicators based on autocatalysis, on thioester chemistry, on organic molecules adsorbed on pyrite? This exciting question is still open. A major problem lies in the fact that we remain ignorant of the true historical facts on Earth from the time when life started.

Life beyond Earth

The main constituents of terrestrial life, i.e. water and organic molecules, are widespread in the universe. Primary organic chemistry is very active in interstellar space. So far, 83 different organic molecules have been identified by RADIOASTRONOMY.

The most important identifications for prebiotic chemistry are probably are hydrogen cyanide, formaldehyde and cyanamide. Although there is little basis for speculating that interstellar organic molecules arrived intact at the prebiotic Earth's surface, there is growing interest in the possibility that interstellar molecules may be preserved intact in comets and in altered form in carbonaceous meteorites.

The molecules which allowed the emergence of terrestrial life appear to be universal. On Earth, they were subjected to a given set of pressure and temperature constraints. Do similar constraints exist elsewhere?

Life on Mars?

MARS mapping by Mariner 9 and Viking 1 and 2 revealed channels resembling dry river beds. Three major classes of channels were identified: (i) dendritic runoff channels and valleys primarily associated with cratered terrain older than 3.8 Gyr and which are generally associated with fluvial water erosion; (ii) outflow channels suggestive of large-volume flows in cataclysmic events; (iii) fretted channels which are steep-walled with smooth flat floors suggestive of erosion by

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

debris flows (McKay 1998). The inventory of the total amount of water that may have existed on the surface of Mars is difficult to estimate and varies from some meters to several hundred meters. The climatic conditions required for the formation of the valley networks are also poorly understood. The most plausible explanation is a relatively thick CO_2 atmosphere (1–5 bar) in the early history of Mars, giving rise to a greenhouse effect which would have allowed for mean global surface temperature to remain above the freezing point of water. Carr suggested recently that the valley networks, like the fretted channels, formed mainly by mass wasting, aided by groundwater seepage into the mass-wasted debris, between 3.8 and 3.7 Gyr ago. Therefore, it is generally considered that liquid water has been restricted to the very early stages of Martian history. By about 3.8 Gyr ago, most of the atmospheric CO_2 was probably irreversibly lost due to carbonate formation and pressure and temperature declined. However, the presence of extensive coastlines at the border of the northern lowlands where the Valles flow supports the presence of a large ocean in the northern hemisphere. This northern ocean could possibly have been active in epochs as young as Middle Amazonian, 500 million years ago. On the other hand, several features suggest the intermittent presence of water on the surface of Mars. Outflow channels have been active in Maja and Ares Valles (Late Hesperian), in Kasei and Mangala Valles (Early Amazonian) and at Elysim (Middle Amazonian). Lacustrine deposits show the same range of age.

The early histories of Mars and Earth clearly show similarities. Geological observations collected from Martian orbiters suggest that liquid water was once stable on the Mars surface, attesting to the presence of an atmosphere capable of deccelerating carbonaceous micrometeorites. Therefore, chemical evolution may have been possible on Mars. The Viking 1 and 2 lander missions were designed to address the question of extant life on Mars. Three experiments were selected to detect metabolic activity such as photosynthesis, nutrition and respiration of potential microbial soil communities. The results were ambiguous since, although 'positive' results were obtained, no organic carbon was found in the Martian soil by gas chromatography–mass spectrometry. It was concluded that the most plausible explanation for these results was the presence, at the Martian surface, of highly reactive oxidants like H_2O_2 which would have been photochemically produced in the atmosphere. The Viking lander could not sample soils below 6 cm and therefore the depth of this apparently organic-free and oxidizing layer is unknown. It has been estimated that the depth of diffusion for H_2O_2 is less than 3 m. Direct photolytic processes can also be responsible for the dearth of organics at the Martian surface.

The alpha proton x-ray spectrometer (APXS) on board the rover of the Mars Pathfinder mission in 1997 measured the chemical composition of six soils and five rocks at the Ares Vallis landing site. Some rocks are similar to terrestrial andesites but it is not certain that these rocks are igneous. The texture of other rocks are difficult to interpret and might be sedimentary or metamorphic.

Although the Viking missions were disappointing in the first instance for EXOBIOLOGY, in the long run the programme has proven extremely beneficial for the investigation of the possibility of life on Mars. Prior to Viking it had been apparent that there was a small group of meteorites, all of igneous origin, called SNC METEORITES (after their type specimens Shergotty, Nakhla and Chassigny) that had comparatively young crystallization ages equal to or less than 1.3 Gyr. One of these meteorites, EETA 79001, was found on Antarctica in 1979. It had, trapped within glass pockets, gas which both compositionally and isotopically matched, in all respects, the make-up of the Martian atmosphere as measured by the mass spectrometer utilized for assessing the soil for the presence of organic compounds. The data provide a very strong argument that at least that particular SNC meteorite comes for Mars, thus supporting the circumstantial conclusion that materials of a young age must have derived from a planetary-sized body. There are now twelve SNC meteorites known in total; others were found more recently on the Antarctic Ice Cap including one of much older age, ALH 84001. They can be all shown to be related by comparing their oxygen isotopic compositions. Only these twelve specimens (out of a total of *ca* 20 000 meteorites) define a correlation line of slope one half on a plot of $\delta^{18}O$ versus $\delta^{17}O$ with $\delta^{17}O = 0.321 \pm 0.013‰$, i.e. displaced from the Earth reference line.

The two SNC meteorites EETA79001 and ALH84001 supply new and highly interesting information. A subsample of EETA79001 excavated from deep within the meteorite has been subjected to stepped-combustion. The CO_2 release from 200 °C to 400 °C suggests the presence of organic molecules. The carbon is enriched in ^{12}C with $\delta^{13}C$ of about –27‰. The difference between organic matter and carbonates in Martian meteorites is greater than the shift seen on Earth which could also be indicative of biosynthesis but some as yet unknown reason cannot be ruled out. McKay *et al* (1996) reported the presence of PAHs, carbonates globules and ovoid features which may represent a signature of relic biogenic activity on Mars but today this biological interpretation has almost been abandoned.

Even if the evidence for ancient life in ALH84001 is not established, the two Martian meteorites show the presence of organic molecules, suggesting that the ingredients required for the emergence of a primitive life may have been present on the surface of Mars. Therefore, it is tempting to consider that microorganisms may have

Dirac House, Temple Back, Bristol, BS21 6BE, UK

developed on Mars until liquid water disappeared. Since Mars probably had no plate tectonics and since liquid water seems to have disappeared from the Mars surface very early, the Martian sub-surface perhaps keeps a frozen record of the very early forms of a terrestrial-like life. American, Japanese and European space agencies have planned a very intensive exploration of Mars. Exobiology interests are included especially in the analysis of samples from sites where the environmental conditions may have been favorable for the preservation of evidence of possible prebiotic or biotic processes. The NASA program included Mars Polar Lander (launched in January 1999, but failed in December 1999) which was intended to land near the southern polar ice cap and analyze some soil samples. Mars 2001 Lander/Rover, to be launched in April 2001, will deliver a small instrumented rover 'Marie-Curie' similar to Sojourner for *in situ* analyses. Mars 2003 Lander/Rover (Spring 2003) will deliver a more sophisticated rover for sample analysis and acquisition as part of the NASA–CNES Mars 05 Sample Return mission. The Martian samples collected both in 2003 and 2005 will be sent into low Martian orbit by two distinct mini-rockets and finally brought back to Earth in 2008. ESA has led a study to design a multi-user integrated suite of instruments for the search for evidence of life on Mars. The priority has been given to the *in situ* organic and isotopic analysis of samples obtained by subsurface core drilling. The multi-user package is expected to be mounted on the 2005 Mars Sample return lander. A first version of the ESA Mars Exobiology integrated package could be launched in June 2003 as part of the ESA Mars Express mission.

Life within Europa's ocean?

EUROPA appears as one of the most enigmatic of the Galilean satellites. With a mean density of about 3.0 g cm^{-3}, the Jovian satellite should be dominated by rocks. Ground-based spectroscopy, combined with gravity data, suggests that the satellite has an icy crust roughly 150 km thick and a rocky interior. The Voyager images showed very few impact craters on Europa's surface, indicating recent, and probably continuing, resurfacing by cryovolcanic and tectonic processes. The Voyager spacecraft also revealed that Europa's surface is crossed by numerous intersecting ridges and dark bands. It has been suggested that Europa's thin outer ice shell might be separated from the silicate interior by a liquid water layer, prevented from freezing by tidal heating as the result of the variation of the gravitational field across the body of the satellite. Heat transfer from the core to the bottom of the ocean, similar to thermal vents in terrestrial oceans, is another possible source of thermal energy. Although the existence of such an ocean is still uncertain, the last images from Galileo showing evidence for mobile icebergs support the presence of liquid water at shallow depths below the surface, either today, or at some time in the past (Carr *et al* 1998). If liquid water is present within Europa, it is quite possible that it includes organic matter derived from thermal vents. Terrestrial-like prebiotic organic chemistry and primitive life may therefore have developed in Europa's ocean. If Europa maintained tidal and/or hydrothermal activity in its subsurface until now, it is possible that bacterial activity is still present. Thus, the possibility of an extraterrestrial life present in the hypothetical ocean of Europa must be seriously considered. The most likely sites for extant life would be at hydrothermal vents below the most recently resurfaced area. To study this directly would require making a borehole through the ice in order to deploy a robotic submersible. On the other hand, biological processes in and around hydrothermal vents could produce biomarkers that would be erupted as traces in cryovolcanic eruptions and thereby be available at the surface for *in situ* analysis or sample return. Mineral nutrients delivered through cryovolcanic eruption would make the same locations the best candidates for photosynthetic life.

What about Titan?

TITAN's atmosphere was revealed mainly by the Voyager 1 mission in 1980, which yielded the bulk composition (90% molecular nitrogen and about 1–8% methane). Also, a great number of trace constituents were observed in the form of hydrocarbons (acetylene, ethane, ethylene, etc), nitriles (HCN, C_2N_2, HC_3N) and oxygen compounds (CO and CO_2). Titan is the only other object in our solar system to bear a resemblance to our own planet in terms of atmospheric pressure (1.5 bar) and carbon/nitrogen chemistry (Raulin 1998). It represents, therefore, a natural laboratory to study the formation of complex organic molecules on a planetary scale and over geological times. The ISO satellite has recently detected tiny amounts of water vapour in the higher atmosphere, but Titan's surface temperatures (94 K) are much too low to allow the presence of liquid water. Although liquid water is totally absent, the satellite provides a unique milieu to study, *in situ*, the products of the fundamental physical and chemical interactions driving a planetary organic chemistry. Titan also serves as a reference laboratory to study, by default, the role of liquid water in exobiology.

The Cassini–Huygens spacecraft launched in October 1997 will arrive in the vicinity of Saturn in 2004 and perform several flybys of Titan making spectroscopic, imaging, radar and other measurements. A descent probe will penetrate the atmosphere and will systematically study the organic chemistry in Titan's geofluid. During 150 min, *in situ* measurements will provide detailed analysis of the organics present in the air, in the aerosols and at the surface.

Arguments in favor of universal life

Arguments can be taken from the study of the origins of terrestrial life. Terrestrial life probably appeared between 4 and 3.8 billion years ago when some organic molecules processed by liquid water began to transfer their chemical information and to evolve by making a few accidental transfer errors. Schematically, the prebiotic condition can be compared to spare pieces of a robot. By chance, some pieces assembled to form a robot capable of assembling other spare pieces to form a second identical robot, etc. Sometimes, a minor error in the building generated more efficient robots. The number of pieces required for the first robot is still unknown. The pieces have been erased by plate tectonics, the permanent presence of liquid water, the unshielded solar ultraviolet radiation and by life itself. If the number was small, life must arise on any body presenting environmental conditions similar to those which prevailed on the primitive Earth because simple chemistry is reproducible. If the number of pieces was large, then life is probably a very rare event, perhaps restricted to our planet. The idea of a primordial simplicity is supported by chemists who found that the spontaneous formation of the RNA sugar ribose under prebiotic conditions is very difficult. They consider now that primitive life was probably simpler than a cell and even than RNA. A simple self-replicating system was probably more robust and offered better chances to resist cataclysmic impacts which might have periodically sterilized the Earth during heavy bombardment. A simple primitive life would be more easily extrapolatable to another celestial body.

Biologists have shown that bacterial life can survive under extreme conditions. Life has continued to develop very well in water which is very acidic, alkaline, or is a strong brine solution. It has also survived and flourished in water at high pressure and at temperatures above 100 °C (Stetter 1998). A flourishing biosphere has been discovered a kilometer deep below the surface of the Earth. Even the space environment is not so harmful. The idea that life could migrate in space, known as panspermia, was originally put forward by Richter and Arrhenius. Recent discoveries have given new support to this idea. These are: (i) the identification of meteorites of lunar and probably also of Martian origin; (ii) the probability of small particles reaching escape velocities by the impact of large meteorites on a planet; (iii) the ability of bacterial spores to survive the shock waves of a simulated meteorite impact; (iv) the high UV resistance of microorganisms at the low temperature of deep space; (v) the high survival rate of bacterial spores over extended periods in space, provided they are shielded against the intense solar ultraviolet radiation or are coated by a mantle of absorbing material which attenuates the solar UV radiation (Horneck 1995). Panspermia will not tell us how life started in another star system but may contribute to distribute life in the universe.

Delivery of extraterrestrial organic molecules is of special interest since it can still be studied today. Such an import process in the early Earth only required an atmosphere to decelerate the particles. Such an atmosphere existed 3.8 billion years ago as documented by geological clues including the Greenland sediments. We have clear evidence that water existed in substantial amounts on the surface of Mars at some earlier epoch, attesting to the presence of an atmosphere capable of decelerating micrometeorites. Therefore, primitive life might also have developed on Mars. How long water was present at the surface is unknown. Nor do we know if water still exists in subsurface aquifers, although there are clear indications of the existence of large permafrost regions and of old water flows out of associated areas. Given the discovery of a flourishing biosphere even a kilometer deep below the surface of the Earth, it would be possible that a similar vast microbial community could still be present below the surface of Mars, having long ago retreated into that ecological niche following the disappearance of the surface water environment. The possibility that life may have evolved on Mars during an early period when water existed on the surface and that life may still exist deep below the surface, marks it as a prime candidate in a search for life beyond the Earth. Finding an extinct terrestrial-like life on Mars would be a major discovery. It would indicate that terrestrial life started with a rather simple set of autocatalytic molecules. If, by a stroke of good fortune, it could be shown that the Martian life used D-amino acids, for example, this would exclude any ancient panspermia from Mars to the Earth and would leave the sign of terrestrial homochirality to a pure chance event. Within the solar system, Europa may have an ocean of liquid water beneath its icy crust as suggested by data and theory. If submarine volcanism exists on Europa, the question arises of whether such activity could support life as in volcano–hydrothermal sites on the Earth's seafloor. New planets have been recently discovered beyond the solar system (see EXOPLANETS by Jean Schneider). How to detect extrasolar life on these planets will probably be a formidable challenge for astronomers and radioastronomers in the next century. The detection of water and ozone (an easy detectable telltale signature of oxygen) in the atmosphere will be a strong indication but not an absolute proof. The detection of an electromagnetic signal (the SETI programme) would be more convincing but probably more problematic. Such discoveries would overjoy chemists, who suspect that life is universal because organic molecules and water are universal, but who need experimental proof to claim it.

Light

Electromagnetic radiation of those wavelengths to which the human eye responds, i.e. from just below 400 nanometers (4×10^{-7} m, 0.4 microns, or 4000 angstroms) to just over 700 nm. Different wavelengths within this range correspond to different colors as perceived by the eye. In order of decreasing wavelength are red, orange, yellow, green, blue, indigo, and violet. Wavelengths shorter than visible are referred to as ultraviolet, wavelengths longer than red are infrared. Light may also be regarded as particles, or photons, the longer-wavelength radiation corresponding to lower-energy photons.

In common with other types of electromagnetic radiation, light travels in a vacuum at a speed of about 300 000 km s^{-1}.

Light Element Nucleosynthesis

The early universe was hot and dense behaving as a cosmic nuclear reactor during the first 20 min of its evolution. It was, however, a 'defective' nuclear reactor, expanding and cooling very rapidly. As a result, only a handful of the lightest nuclides were synthesized before the density and temperature dropped too low for the nuclear reaction rates to compete with the universal expansion rate (see UNIVERSE: THERMAL HISTORY). After hydrogen (^{1}H $\equiv$ protons) the next most abundant element to emerge from the Big Bang is helium (^{4}He $\equiv$ alpha particles). Isotopes of these nuclides (deuterium and helium-3) are the next most abundant primordially. Then there is a large gap to the much lower abundance of lithium-7. The relative abundances of all other primordially-produced nuclei are very low, much smaller than their locally observed (or, currently observable) abundances. After a brief description of the early evolution of the universe emphasizing those aspects most relevant to primordial, or 'big bang' nucleosynthesis (BBN), the predicted abundances of the light nuclides will be presented as a function of the one 'free' parameter (in the simplest, 'standard' model: SBBN), the nucleon (or 'baryon') abundance. Then, each element will be considered in turn in a confrontation between the predictions of SBBN and the observational data. At present (summer 1999) there is remarkable agreement between the SBBN predictions of the abundances of four nuclides (D, ^{3}He, ^{4}He and ^{7}Li) and their primordial abundances inferred from the observations. However, there are some hints that this concordance of the hot big bang model may be imperfect, so we will also explore some variations on the theme of the standard model with regard to their modifications of the predicted primordial abundances of the light elements.

In the simplest, standard, hot big bang model the currently observed large-scale isotropy and homogeneity of the universe is assumed to apply during earlier epochs in its evolution (see COSMOLOGY: STANDARD MODEL). Given the currently observed universal expansion and the matter and radiation (CBR: 'cosmic background radiation', the 2.7 K 'black body radiation') content, it is a straightforward application of classical physics to extrapolate back to earlier epochs in the history of the universe (see COSMIC MICROWAVE BACKGROUND). At a time of order 0.1 s after the expansion began the universe was filled with a hot, dense plasma of particles. The most abundant were photons, electron–positron pairs, particle–antiparticle pairs of all known 'flavors' of neutrinos (ν_e, ν_μ and ν_τ) and trace amounts of neutrons and protons ('nucleons' or 'baryons'). At such early times the thermal energy of these particles was very high, of order a few MeV. With the exception of the nucleons, it is known or assumed that all the other particles present were extremely relativistic at this time. Given their high energies (and velocities close to, or exactly equal to, the speed of light) and high densities, the electroweak interactions among these particles were sufficiently rapid to have established thermal equilibrium. As a result, the numbers and distributions (of momentum and energy) of all these particles are accurately predicted by well-known physics.

Nucleosynthesis in the early universe

The primordial yields of light elements are determined by the competition between the expansion rate of the universe (the Hubble parameter H) and the rates of the weak and nuclear reactions (see HUBBLE CONSTANT). It is the weak interaction, interconverting neutrons and protons, that largely determines the amount of ^{4}He which may be synthesized, while detailed nuclear reaction rates regulate the production (and destruction) of the other light elements. In the standard model of cosmology the early expansion rate is fixed by the total energy density ρ,

$$H^2 = 8\pi G\rho/3 \tag{1}$$

where G is Newton's gravitational constant. In the standard model of particle physics the early energy density is dominated by the lightest, relativistic particles. For the epoch when the universe is a few tenths of a second old and older, and the temperature is less than a few MeV,

$$\rho = \rho_\gamma + \rho_e + N_\nu \rho_\nu \tag{2}$$

where ρ_γ, ρ_e and ρ_ν are the energy densities in photons, electrons and positrons, and massless neutrinos and antineutrinos (one species), respectively; N_ν is the number of massless (or, very light: $m_\nu \ll 1$ MeV) neutrino species which, in standard BBN, is exactly 3. In considering variations on the theme of the standard model, it is useful to allow N_ν to differ from 3 to account for the presence of 'new' particles and/or any suppression of the standard particles (e.g. if the τ neutrino should have a large mass). Since the energy density in relativistic particles scales as the fourth power of the temperature, the early expansion rate scales as the square of the temperature with a coefficient that depends on the number of different relativistic species. The more such species, the faster the universe expands, the earlier (higher temperature) will the weak and nuclear reactions drop out of equilibrium. It is useful to write the total energy density in terms of the photon energy density and g, the equivalent number of relativistic degrees of freedom (i.e. helicity states, modulo the different contributions to the energy density from fermions and bosons),

$$\rho \equiv (g/2)\rho_\gamma . \tag{3}$$

In the standard model at $T \sim 1$ MeV, $g_{SM} = 43/4$. Account may be taken of additional degrees of freedom by comparing their contribution to ρ with that of one additional light neutrino species:

$$\Delta\rho \equiv \rho_{TOT} - \rho_{SM} \equiv \Delta N_\nu \rho_\nu . \tag{4}$$

If the early energy density deviates from that of the standard model, the early expansion rate (or, equivalently,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the age at a fixed temperature) will change as well. The 'speed-up' factor $\xi \equiv H/H_{\rm SM}$ may be related to ΔN_ν by

$$\xi = (\rho/\rho_{\rm SM})^{1/2} = (1 + 7\,\Delta N_\nu/43)^{1/2}. \qquad (5)$$

As we will see shortly, the ^{4}He abundance is very sensitive to the early expansion rate while the abundances of the other light nuclides depend mainly on the nuclear reaction rates which scale with the nucleon (baryon) density. Since the baryon density is always changing as the universe expands, it is convenient to distinguish between models with different baryon densities using a dimensionless parameter which either is conserved or, changes in a known and calculable fashion. From the very early universe until now the number of baryons in a comoving volume has been preserved and the same is roughly true for photons since the end of BBN. Therefore, the ratio of number densities of baryons ($n_{\rm B}$) and photons (n_γ) provides just such a measure of the universal baryon abundance:

$$\eta \equiv (n_{\rm B}/n_\gamma)_0 \qquad \eta_{10} \equiv 10^{10}\eta. \qquad (6)$$

The universal density of photons at present (throughout this article the present epoch is indicated by the subscript '0') is dominated by those in the CBR (for $T_0 = 2.73$ K, $n_{\gamma 0} = 412$ cm^{-3}) so that the baryon density parameter $\Omega_{\rm B} \equiv (\rho_{\rm B}/\rho_{\rm c})_0$, the ratio of the present baryon density ($\rho_{\rm B}$) to the present critical density ($\rho_{\rm c}$), may be related to η and the present value of the Hubble parameter $H_0 \equiv 100h$ km s^{-1} Mpc^{-1},

$$\eta_{10} = 273\Omega_{\rm B}h^2. \qquad (7)$$

It should be noted that prior to electron–positron annihilation there were fewer photons in every comoving volume (by a factor very close to 4/11); this is automatically accounted for in all numerical BBN codes. It is simply a matter of consensus and convenience that the baryon abundance is quoted in terms of its present value.

In SBBN (i.e. $N_\nu = 3$) the abundances of the light nuclides synthesized primordially depend on only one 'free' parameter, η. SBBN is thus 'overconstrained' since one value (or, a narrow range of values set by the observational and theoretical reaction rate uncertainties) of η must account consistently for the primordial abundances of D, ^{3}He, ^{4}He and ^{7}Li. At the same time this value or range of η must be consistent with current estimates of (or, bounds to) the present baryon density. For these reasons BBN is one of the key pillars supporting the edifice of the standard model of cosmology and it is the only one which offers a glimpse of the earliest evolution of the universe. In the following we will first identify the key landmarks in the first 20 min in the evolution of the universe in order to identify the physical processes responsible for determining the primordial abundances of the light nuclides. Then, after presenting the SBBN predictions (as a function of η; see figure 1) we will review the current status of the observational data, as well as the steps necessary in order to go from 'here and now' to 'there and then' when using the data to infer the true primordial abundances. Then we will be in a position to assess the consistency of the standard model.

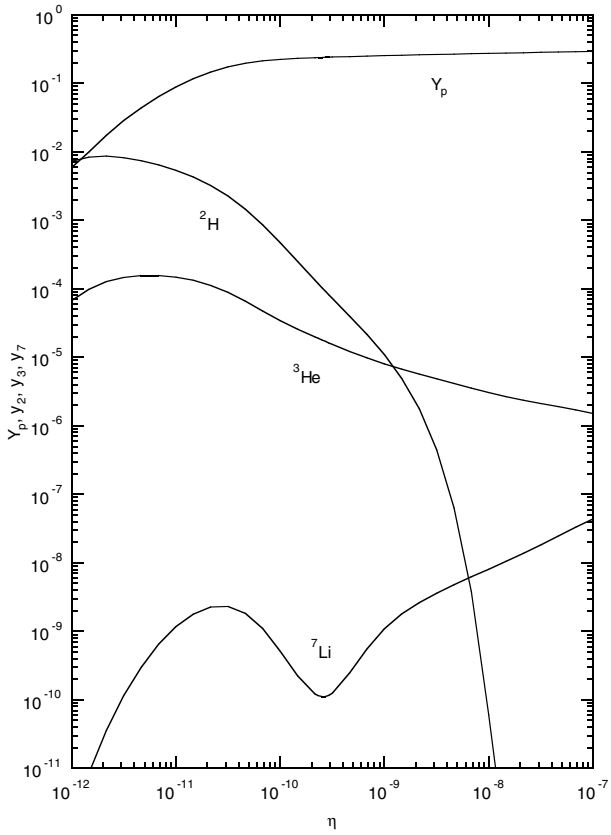

Figure 1. The predicted primordial abundances as a function of η. $Y_{\rm p}$ is the ^{4}He mass fraction while $y_{2\rm P}$, $y_{3\rm P}$, $y_{7\rm P}$ are the number density ratios to hydrogen of D, ^{3}He and ^{4}He respectively.

Weak equilibrium and the ^{4}He abundance

Consider now those early epochs when the universe was only a few tenths of a second old and the radiation filling it was at a temperature (thermal energy) of a few MeV. According to the standard model, at those early times the universe was a hot, dense 'soup' of relativistic particles (photons, $e^\pm$ pairs, three 'flavors' (e, μ, τ) of neutrino–antineutrino pairs) along with a trace amount (at the level of a few parts in 10^{10}) of neutrons and protons. At such high temperatures and densities both the weak and the nuclear reaction rates are sufficiently rapid (compared with the early universe expansion rate) that all particles have come to equilibrium. A key consequence of equilibrium is that the earlier history of the evolution of the universe is irrelevant for an understanding of BBN. When the temperature drops below a few MeV the weakly interacting neutrinos effectively decouple from the photons and $e^\pm$ pairs, but they still play an important role in regulating the neutron-to-proton ratio.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

At high temperatures, neutrons and protons are continuously interconverting via the weak interactions: $n + e^+ \leftrightarrow p + \bar{\nu}_e$, $n + \nu_e \leftrightarrow p + e^-$, and $n \leftrightarrow p + e^- + \bar{\nu}_e$. When the interconversion rate is faster than the expansion rate, the neutron-to-proton ratio tracks its equilibrium value, decreasing exponentially with temperature ($n/p = e^{-\Delta m/T}$, where $\Delta m = 1.29$ MeV is the neutron–proton mass difference). A comparison of the weak rates with the universal expansion rate reveals that equilibrium may be maintained until the temperature drops below ~0.8 MeV. When the interconversion rate becomes less than the expansion rate, the n/p ratio effectively 'freezes out' (at a value of ≈1/6), thereafter decreasing slowly, mainly as a result of free neutron decay.

Although n/p freeze-out occurs at a temperature below the deuterium binding energy, $E_B = 2.2$ MeV, the first link in the nucleosynthetic chain, $p + n \rightarrow D + \gamma$, is ineffective in jump-starting BBN since the photodestruction rate of deuterium ($\propto n_\gamma e^{-E_B/T}$) is much larger than the deuterium production rate ($\propto n_B$) owing to the very large universal photon-to-baryon ratio ($\gtrsim 10^9$). Thus, the universe must 'wait' until there are so few sufficiently energetic photons that deuterium becomes effectively stable against photodissociation. This occurs for temperatures $\gtrsim$80 keV, at which time neutrons are rapidly incorporated into ^{4}He with an efficiency of 99.99%. This efficiency is driven by the tight binding of the ^{4}He nucleus, along with the roadblock to further nucleosynthesis imposed by the absence of a stable nucleus at mass 5. By this time ($T \gtrsim 80$ keV), the n/p ratio has dropped to ~1/7, and simple counting (2 neutrons in every ^{4}He nucleus) yields an estimated primordial ^{4}He mass fraction

$$Y_P \approx \frac{2(n/p)}{1+n/p} \approx 0.25. \qquad (8)$$

As a result of its large binding energy and the gap at mass 5, the primordial abundance of ^{4}He is relatively insensitive to the nuclear reaction rates and, therefore, to the baryon abundance (η). As may be seen in figure 1, while η varies by orders of magnitude, the predicted ^{4}He mass fraction, Y_P, changes by factors of only a few. Indeed, for $1 \leq \eta_{10} \leq 10$, $0.22 \leq Y_P \leq 0.25$. As may be seen in figures 1 and 2, there is a very slight increase in Y_p with η. This is mainly due to BBN beginning earlier, when there are more neutrons available to form ^{4}He, if the baryon-to-photon ratio is higher. The increase in Y_p with η is logarithmic; over most of the interesting range in η, $\Delta Y_p \approx 0.01\,\Delta\eta/\eta$.

The ^{4}He abundance is, however, sensitive to the competition between the universal expansion rate (H) and the weak interaction rate (interconverting neutrons and protons). If the early universe should expand faster than predicted for the standard model, the weak interactions will drop out of equilibrium earlier, at a higher temperature, when the n/p ratio is higher. In this case, more neutrons will be available to be incorporated into ^{4}He and Y_p will increase. Numerical calculations show that, for a modest speed-up ($\Delta N_\nu \lesssim 1$), $\Delta Y_p \approx 0.013\,\Delta N_\nu$. Hence, constraints on Y_p (and η) lead directly to bounds on ΔN_ν and on particle physics beyond the standard model [1].

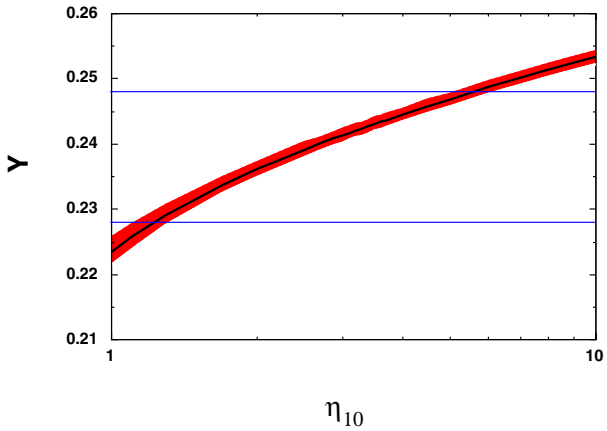

Figure 2. The predicted ^{4}He abundance (solid curve) and the 2σ theoretical uncertainty [2]. The horizontal lines show the range indicated by the observational data.

It should be noted that the uncertainty in the BBN-predicted mass fraction of ^{4}He is very small and almost entirely dominated by the (small) uncertainty in the n–p interconversion rates. These rates may be 'normalized' through the neutron lifetime, τ_n, whose current standard value is 887 ± 2 s (actually, 886.7 ± 1.9 s). To very good accuracy, a 1 s uncertainty in τ_n corresponds to an uncertainty in Y_p of order 2×10^{-4}. At this tiny level of uncertainty it is important to include finite-mass, zero- and finite-temperature radiative corrections, and Coulomb corrections to the weak rates. However, within the last few years it has emerged that the largest error in the BBN-prediction of Y_p was due to a too large time-step in the numerical code. With this now under control, it is estimated that the residual theoretical uncertainty (in addition to that from the uncertainty in τ_n) is of the order of 2 parts in 10^4. Indeed, a comparison of two major, independent BBN codes reveals agreement in the predicted values of Y_p to 0.0001 ± 0.0001 over the entire range $1 \leq \eta_{10} \leq 10$. In figure 2 is shown the BBN-predicted ^{4}He mass fraction, Y_p, as a function of η; the thickness of the band is the $\pm 2\sigma$ theoretical uncertainty. For $\eta_{10} \gtrsim 2$ the 1σ theoretical uncertainty in Y_p is $\lesssim 6 \times 10^{-4}$. As we will soon see, the current observational uncertainties in Y_p are much larger (see, also, figure 2).

Deuterium—the ideal baryometer

As may be seen in figure 1, the deuterium abundance (the ratio, by number, of deuterium to hydrogen: hereinafter, $(D/H)_P \equiv y_{2P}$) is a monotonic, rapidly decreasing function of the baryon abundance η. The reason for this behavior is easily understood. Once BBN begins in earnest, when the temperature drops below ~80 keV, D is rapidly burned to ^{3}H, ^{3}He and ^{4}He. The higher the baryon abundance, the faster the burning and the less D survives. For η_{10} in the 'interesting' range 1–10, y_{2P} decreases with the ~1.6

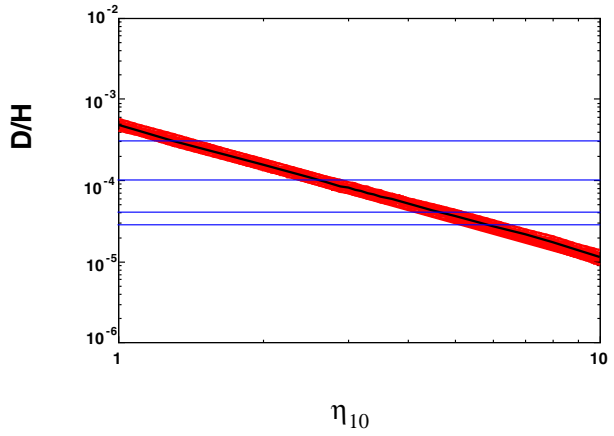

Figure 3. The predicted D/H abundance (solid curve) and the 2σ theoretical uncertainty [2]. The horizontal lines show the range indicated by the observational data for both high D/H (upper two lines) and low D/H (lower two lines).

power of η. As a result, a 10% error in y_{2P} corresponds to only a 6% error in η. This strong dependence of y_{2P} on η_{10}, combined with the simplicity of the evolution of D/H in the epochs following BBN, is responsible for the unique role of deuterium as a baryometer [3]. Because almost all the relevant reaction cross sections are measured in the laboratory at energies comparable with those of BBN, the theoretical uncertainties in the BBN-predicted abundance of deuterium is quite small, 8–10% for most of the interesting η range shown in figure 3.

Deuterium and helium-4 are complementary, forming the crucial link in testing the consistency of BBN in the standard model. While the primordial D abundance is very sensitive to the baryon density, the primordial ^{4}He abundance is relatively insensitive to η. Deuterium provides a bound on the universal baryon density while helium-4 constrains the early expansion rate of the universe, offering bounds on particle physics beyond the standard model.

Helium-3—complicated evolution

As may be seen in figure 1, the predicted primordial abundance of ^{3}He behaves similarly to that of D, decreasing monotonically with η. Again, the reason is the same: ^{3}He is being burned to the more tightly bound nucleus ^{4}He. The higher the nucleon abundance, the faster the burning and the less ^{3}He survives. In contrast to the behavior of D/H versus η, the decrease of ^{3}He/H with increasing η is much slower. This is simply a reflection of the much tighter binding of ^{3}He compared with D. Although the BBN predictions for the abundance of ^{3}He have similarly small uncertainties (8–10%) to those of D, it is much more difficult to exploit the observations of ^{3}He to test and constrain BBN. The complication is the evolutionary history of the ^{3}He abundance since BBN.

Although any deuterium cycled through stars is burned to ^{3}He during the stars' pre-main-sequence evolution, ^{3}He will survive in the cooler stellar exteriors while being destroyed in the hotter interiors. For the more abundant lower-mass stars which are cooler, a larger fraction of prestellar ^{3}He (along with the ^{3}He produced from prestellar D) survives. Indeed, for sufficiently low-mass stars (less than a few solar masses) incomplete burning actually leads to a buildup of newly synthesized ^{3}He (to be contrasted with the prestellar D and ^{3}He) which may—or may not—be returned to the interstellar medium. In fact, some PLANETARY NEBULAE are observed to be highly enriched in ^{3}He. So, the evolution of ^{3}He is complex with stellar destruction competing with primordial and stellar production. Indeed, if all low-mass stars were as prolific producers of ^{3}He as indicated by some planetary nebulae, the solar system and local interstellar medium abundances of ^{3}He should far exceed those inferred from observations. Thus, at least some low-mass stars must be net destroyers of ^{3}He. Given this necessarily complex and uncertain picture of production, destruction and survival, it is difficult to use current observational data to infer the primordial abundance of ^{3}He. Unless and until ^{3}He is observed in high-redshift (i.e. early universe), low-metallicity (i.e. nearly unevolved) systems, it will provide only a weak check on the consistency of BBN.

Lithium-7– the lithium valley

The trend of the BBN-predicted primordial abundance of lithium (almost entirely ^{7}Li) with η is more 'interesting' than that of the other light nuclides (see figures 1 and 4). The 'lithium valley', centered near $\eta_{10} \approx 2$–3, is the result of the competition between production and destruction in the two paths to mass 7 synthesis. At relatively low baryon abundance ($\eta_{10} \lesssim 2$) mass 7 is mainly synthesized as ^{7}Li via $^3\mathrm{H} + {}^4\mathrm{He} \rightarrow {}^7\mathrm{Li} + \gamma$. As the baryon abundance increases at low η, ^{7}Li is destroyed rapidly by $(\mathrm{p}, \gamma)2\alpha$ reactions, hence the decrease in $(\mathrm{Li/H})_P \equiv y_{7P}$ with increasing η seen (at low η) in figures 1 and 4. Were this the only route to primordial synthesis of mass 7, this monotonic trend would continue, similar to those for D and ^{3}He. However, mass 7 may also be synthesized via $^3\mathrm{He} + {}^4\mathrm{He} \rightarrow {}^7\mathrm{Be} + \gamma$. The ^{7}Be will later capture an electron to become ^{7}Li. This channel is very important because it is much easier to destroy ^{7}Li than ^{7}Be. As a result, for relatively high baryon abundance ($\eta_{10} \gtrsim 3$) the latter channel dominates mass 7 production and y_{7P} increases with increasing η.

As may been seen in figure 4, the BBN-predicted uncertainties for y_{7P} are much larger than those for D, ^{3}He or ^{4}He. In the interval $1 \leq \eta_{10} \leq 10$ the 1σ uncertainties are typically ∼20%, although in a narrow range of η near the bottom of the 'valley' they are somewhat smaller (∼12–15%).

From here and now to there and then

To test the consistency of SBBN requires that we confront the predictions with the primordial abundances of the light nuclides which, however, are not observed but, rather, are inferred from observations. The path from the observational data to the primordial abundances is long

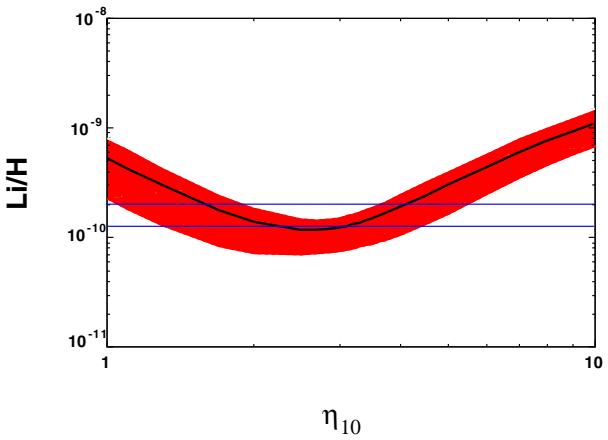

Figure 4. The predicted ^{7}Li abundance (solid curve) and the 2σ theoretical uncertainty [2]. The horizontal lines show the range indicated by the observational data.

and twisted and often fraught with peril. In addition to the usual statistical and systematic uncertainties, it is crucial to forge a connection from 'here and now' to 'there and then', i.e. to relate the derived abundances to their primordial values. It is indeed fortunate that each of the key elements is observed in different astrophysical sites using very different astronomical techniques. Also, the corrections for chemical evolution differ among them and, even more important, they can be minimized. For example, deuterium (and hydrogen) is mainly observed in cool, neutral gas (so-called H I REGIONS) via UV absorption from the atomic ground state (the Lyman series), while radio telescopes allow helium-3 to be studied utilizing the analog of the hydrogen 21 cm line for singly ionized ^{3}He in regions of hot, ionized gas (so called H II regions). Helium-4 is probed using the emission from its optical recombination lines formed in H II regions. In contrast, lithium is observed in the absorption spectra of warm, low-mass halo stars. With such different sites, with the mix of absorption–emission, and with the variety of telescopes and different detectors involved, the possibility of correlated errors biasing the comparison with the predictions of BBN is unlikely. This favorable situation extends to the obligatory evolutionary corrections. For example, although until recently observations of deuterium were limited to the solar system and the Galaxy, mandating uncertain evolutionary corrections to infer the pregalactic abundance, the Keck and HUBBLE SPACE TELESCOPES have begun to open the window to deuterium in high-redshift, low-metallicity, nearly primordial regions (Lyman-α clouds). Observations of ^{4}He in chemically unevolved, low-metallicity ($\sim$1/50 of solar) extragalactic H II regions permit the evolutionary correction to be reduced to the level of the statistical uncertainties. The abundances of lithium inferred from observations of the very metal-poor halo stars (one-thousandth of solar abundance and even lower) require almost no correction for chemical evolution. On the other hand, as noted earlier, the status of helium-3 is in contrast to that of the other light elements. For this reason, ^{3}He will not be used quantitatively in this article.

The currently very favorable observational and evolutionary situation for the nuclides produced during BBN is counterbalanced by the likely presence of systematic errors in the path from observations to primordial abundances. By their very nature, such errors are difficult—if not impossible—to quantify. In the key case of deuterium there is a very limited set of the most useful data. As a result, and although cosmological abundance determinations have taken their place in the current 'precision' era of cosmology, it is far from clear that the present abundance determinations are truly 'accurate'. Thus, the usual *caveat emptor* applies to any conclusions drawn from the subsequent comparison between the predictions and the data. With this caution in mind the current status of the data will be surveyed in order to infer 'reasonable' ranges for the primordial abundances of the key light elements.

Deuterium

Since deuterium is completely burned away whenever it is cycled through stars, and there are no astrophysical sites capable of producing deuterium in anywhere near its observed abundance [3], any D abundance derived from observational data provides a lower bound to its primordial abundance. Thus, without having to correct for Galactic evolution, the 'here-and-now' deuterium abundance inferred from UV observations along 12 lines of sight in the local interstellar medium (LISM) bounds the 'there-and-then' primordial abundance from below $((\mathrm{D/H})_\mathrm{P} \geq (\mathrm{D/H})_\mathrm{LISM} = (1.5 \pm 0.1) \times 10^{-5})$. As may be seen from figures 1 and 2, any lower bound to primordial D will provide an upper bound to the baryon-to-photon ratio [4].

Solar system observations of ^{3}He permit an independent, albeit indirect, determination of the pre-solar-system deuterium abundance [5]. This estimate of the Galactic abundance some 4.5 Gyr ago, while somewhat higher than the LISM value, has a larger uncertainty ($\mathrm{D/H} = (2.1 \pm 0.5) \times 10^{-5}$ [6]). Within the uncertainty it is consistent with the LISM value suggesting there has been only modest destruction of deuterium in the last 4.5 Gyr. There is also a recent measurement of deuterium in the atmosphere of Jupiter using the Galileo Probe Mass Spectrometer [7] ($\mathrm{D/H} = (2.6 \pm 0.7) \times 10^{-5}$ (see GALILEO MISSION TO JUPITER)).

To further exploit the solar system and/or LISM deuterium determinations to constrain or estimate the primordial abundance would require corrections for the Galactic evolution of D; see GALACTIC EVOLUTION. Although the simplicity of the evolution of deuterium (it is only destroyed) suggests that such correction might be very nearly independent of the details of specific chemical evolution models, large differences remain between different estimates. It is therefore fortunate that

Dirac House, Temple Back, Bristol, BS1 6BE, UK

data on D/H in high-redshift (nearly primordial), low-metallicity (nearly unevolved) Lyman-α absorbers have become available in recent years [8, 9]. It is expected that such systems still retain their original, primordial deuterium, undiluted by the deuterium-depleted debris of any significant stellar evolution. That is the good news. The bad news is that, at present, D abundance determinations are claimed for only three such systems, and that the abundances inferred for two of them (along with a limit to the abundance for a third) appear to be inconsistent with the abundance estimated for the remaining one. Here we have a prime illustration of 'precise', but possibly inaccurate, cosmological data. Indeed, there is a serious obstacle inherent to using absorption spectra to measure the deuterium abundance since the isotope-shifted deuterium absorption lines are indistinguishable from the corresponding lines in suitably velocity-shifted ($-81\,\mathrm{km\,s^{-1}}$) hydrogen. Such 'interlopers' may have been responsible for some of the early claims [8] of a 'high' deuterium abundance [10]. Indeed, an interloper may be responsible for the one surviving high-D claim [11]. At present it seems that only three good candidates for nearly primordial deuterium have emerged from ground- and space-based observations. It may be premature to constrain cosmology on the basis of such sparse data. Nonetheless, the two 'low-D' systems suggest a primordial deuterium abundance consistent with estimates of the pre-Galactic value inferred from LISM and solar system data ($(\mathrm{D/H})_\mathrm{P} = (3.4 \pm 0.25) \times 10^{-5}$ [12]). To illustrate the confrontation of cosmological theory with observational data, this D abundance will be adopted in the following. However, the consequences of choosing the 'high-D' abundance ($(\mathrm{D/H})_\mathrm{P} = (20 \pm 5) \times 10^{-5}$ [11]) will also be discussed.

Helium-4

As the second most abundant nuclide in the universe (after hydrogen), the abundance of ^{4}He can be determined to high accuracy at sites throughout the universe. However, as stars evolve they burn hydrogen to helium and the ^{4}He in the debris of STELLAR EVOLUTION contaminates any primordial ^{4}He. Since any attempt to correct for stellar evolution will be inherently uncertain, it is sensible to concentrate on the data from low-metallicity sites. Extragalactic regions of hot, ionized gas (H II regions) provide such sites, where the helium is revealed via emission lines formed when singly and doubly ionized helium recombines. As with deuterium, current data provide ambiguous estimates of the primordial helium abundance. Since the differences ($\Delta Y = 0.010$) are larger than the statistical uncertainties ($\lesssim \pm 0.003$), systematic errors probably dominate. Among the currently most likely sources of such errors are uncertain corrections for collisional excitation in helium, uncertain corrections for unseen neutral helium and/or hydrogen, and underlying stellar absorption (leading to an underestimate of the true strength of the helium emission lines). In contrast, since the most metal poor of the observed regions have metallicities of order 1/50–1/30 of solar, the extrapolation from the lowest-metallicity regions to truly primordial introduces an uncertainty no larger than the statistical error.

Using published data [13, 14] for 40 low-metallicity regions, one group [15] finds $Y_\mathrm{P} = 0.234 \pm 0.003$. In contrast, from an independent data set of 45 low-metallicity regions another group [16] infers $Y_\mathrm{P} = 0.244 \pm 0.002$. Clearly, these results are statistically inconsistent. It is crucial that high priority be assigned to further H II region observations to estimate or avoid the systematic errors. Until then, since the error budget for Y_P is probably dominated by systematic rather than statistical uncertainties, in what follows a generous range for Y_P will be adopted: $0.228 \leq Y_\mathrm{P} \leq 0.248$.

Lithium-7

Cosmologically interesting lithium is observed in the spectra of nearly 100 very metal poor halo stars [17, 18] (see GALACTIC METAL-POOR HALO). These stars are so metal poor they provide a sample of more nearly primordial material than anything observed anywhere else in the universe; the most metal-poor among them have heavy-element abundances less than one-thousandth of the solar metallicity. However, these halo stars are also the oldest objects in the Galaxy and, as such, have had the most time to modify their surface abundances. So, even though any correction for Galactic evolution modifying their lithium abundances may be smaller than the statistical uncertainties of a given measurement, the systematic uncertainty associated with the dilution and/or destruction of surface lithium in these very old stars could dominate the error budget. There could be additional errors associated with the modeling of the surface layers of these cool, low-metallicity, low-mass stars needed to derive abundances from absorption-line spectra. It is also possible that some of the Li observed in these stars is non-primordial (e.g. that some of the observed Li may have been produced post-BBN by spallation reactions (the breakup of C, N and O nuclei into nuclei of Li, Be and B) or fusion reactions ($\alpha + \alpha$ to form ^{6}Li and ^{7}Li) in cosmic-ray collisions with gas in the ISM). In a recent analysis [19], it is argued that as much as $\sim$0.2 dex of the observed lithium abundance, $A(\mathrm{Li}) \equiv 12 + \log(\mathrm{Li/H})$, could be post-primordial in origin.

The very large data set of lithium abundances measured in the warmer ($T > 5800$ K), more metal-poor ([Fe/H] < -1.3) halo stars defines a plateau (the 'Spite-plateau' [17]) in the lithium abundance–metallicity plane. Depending on the choice of stellar-temperature scale and stellar atmosphere model, the abundance level of the plateau is $A(\mathrm{Li}) = 2.2 \pm 0.1$, with very little dispersion in abundances around this plateau value. The small dispersion provides an important constraint on models which attempt to connect the present surface lithium abundances in these stars to the original lithium abundance in the gas out of which these stars were formed some 10–15 Gyr ago. 'Standard' (i.e. non-rotating) stellar

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

models predict almost no lithium depletion and, therefore, are consistent with no dispersion about the Spite plateau. Although early work on mixing in models of rotating stars was very uncertain, recently stellar models have been constructed which reproduce the angular momentum evolution observed for the much younger, low-mass open cluster stars. These models have been applied to the study of lithium depletion in main sequence halo stars. A well-defined lithium plateau with modest scatter and a small population of 'outliers' (overdepleted stars), consistent with the current data, is predicted for depletion factors between 0.2 dex and 0.4 dex [20].

To err on the side of caution, a generous range for the plateau abundance, $2.1 \leq A(\mathrm{Li}) \leq 2.3$, is adopted. If depletion is absent, this range is consistent with the primordial lithium 'valley' (see figure 4). For depletion $\geq$0.2 dex, the consistent primordial lithium abundances bifurcate and move up into the 'foothills', although a non-negligible contribution from post-BBN lithium could move the primordial abundance back down again (figure 4).

Confrontation of theory with data

In the context of the 'standard' model (three families of massless, or light, two-component neutrinos), the predictions of BBN (SBBN) depend on only one free parameter, the nucleon-to-photon ratio η. The key test of the standard, hot, big bang cosmology is to assess whether there exists a unique value or range of η for which the predictions of the primordial abundances are consistent with the light-element abundances inferred from the observational data. From a statistical point of view it might be preferable to perform a simultaneous fit of the inferred primordial abundances of D, ^{3}He, ^{4}He and ^{7}Li to the SBBN predictions. In this manner the 'best fit' η, along with its probability distribution may be found, and the 'goodness of fit' assessed [21]. However, since systematic uncertainties most likely dominate observational errors at present, the value of this approach is compromised. An alternative approach is adopted here.

As emphasized earlier, deuterium is an ideal baryometer. As a first step the primordial abundance of deuterium inferred from observations at high redshift will be compared with the SBBN prediction to identify a consistent range for η. Then, given this range, the SBBN abundances of ^{4}He and ^{7}Li are predicted and these are compared with the corresponding primordial abundances derived from the observational data. The challenge is to see whether the D-identified range for η leads to consistent predictions for ^{4}He and ^{7}Li. Recall that, because of its complicated evolutionary history, it is difficult to use ^{3}He to test and constrain SBBN. Furthermore, another consistency test is to compare the SBBN-inferred η range with the present baryon density derived from non-BBN observations and theory. Is our model for the very early evolution of the universe consistent with the present universe?

From the two well-observed, high-redshift absorption line systems with 'low D', the estimate adopted for the primordial D abundance is $(\mathrm{D/H})_\mathrm{P} = (2.9 - 4.0) \times 10^{-5}$ (see figure 3). Also shown for comparison in figure 3 is the allowed range of the primordial deuterium abundance suggested by the 'high-D' abundance inferred from observations of one lower-redshift absorption-line system. With allowance for the ~8% uncertainty in the theoretically predicted abundance, the favored range (low D) for η is quite narrow: $\eta_{10} = 5.1 \pm 0.36$. It is clear from figure 4 that, for the baryon abundance in this range, the BBN-predicted lithium abundance is entirely consistent with the Spite plateau value, even if the plateau were raised by ~0.2 dex to allow for modest stellar destruction–dilution or lowered by a similar amount owing to post-BBN production. For this narrow range in η the predicted ^{4}He mass fraction varies very little. For $\eta_{10} \approx 5$, $\Delta Y_\mathrm{P} \approx 0.010\,\Delta\eta/\eta$, so that, including the error in the predicted abundance, $Y_\mathrm{P} = 0.247 \pm 0.001$. As may be verified from figure 2, this is within (albeit at the high end of) the range allowed by the data from the low-metallicity, extragalactic H II regions. Given the current uncertainties in the primordial abundances, SBBN is consistent with 'low-D, high-η'.

The significance of this concordance cannot be underestimated. A glance at figure 1 provides a reminder of the enormous ranges for the predicted primordial abundances. That the simplest hot, big bang cosmological model can account for ('predict') three independent abundances (four with ^{3}He; although ^{3}He has not been employed in this comparison, its predicted abundance is consistent with extant observational data) by adjusting only one free parameter (η) is a striking success. The theory, which is in principle falsifiable, has passed the test. It need not have. Indeed, future observational data coupled to better understanding of systematic errors may provide new challenges. For example, if in the future it should be determined that the primordial helium mass fraction were lower than $Y_\mathrm{P} = 0.245$, this would be inconsistent (within the errors) with the 'low-D, high-η' range derived above. Similarly, if the best estimate for the D-determined η range changed, the comparison performed above should be repeated. With this in mind, what of the 'high-D, low-η' range which has been set aside in the current comparison?

If, in contrast to the deuterium abundance adopted above, the true value were higher, $(\mathrm{D/H})_\mathrm{P} = (10\text{–}30) \times 10^{-5}$, the SBBN-favored range in η would be lower (see figure 3). Accounting for the ~8% uncertainty in the theoretically predicted abundance, $\eta_{10} = 1.7 \pm 0.28$. Inspection of figures 2–4 reveals that, as long as $\eta_{10} \gtrsim 1.1\text{–}1.3$, consistency with ^{4}He and ^{7}Li can be obtained. Hence, for 'high D' as well, the standard model passes the key cosmological test.

Comparison of BBN with non-BBN baryon density estimates

Having established the internal consistency of primordial nucleosynthesis in the standard model, it is necessary to

proceed to the next key test. Does the nucleon abundance inferred from processes which occurred during the first thousand seconds of the evolution of the universe agree with estimates–bounds to the nucleon density in the present universe?

It is a daunting task to attempt to inventory the baryons in the universe. Since many (most?) baryons may be 'dark', such approaches can best set lower bounds to the present ratio of baryons to photons. One such estimate [22] suggests a very weak lower bound on η of $\eta_{10} \geq 0.25$, entirely consistent with the BBN estimates above. Others [23] have used more subjective (although cautious) estimates of the uncertainties, finding a much higher lower bound to the global budget of baryons: $\eta_{10} \geq 1.5$, which is still consistent with the 'low-η' range identified using the high-D results.

A possible challenge to the 'low-η' case comes from an analysis [24] which employed observational constraints on the Hubble parameter, the age of the universe, the structure-formation 'shape' parameter and the x-ray cluster gas fraction to provide non-BBN constraints on the present density of baryons, finding that $\eta_{10} \geq 5$ may be favored over $\eta_{10} \leq 2$. Even so, a significant low-η, high-D range still survives.

Cosmology constrains particle physics

Limits on particle physics beyond its standard model are mostly sensitive to the bounds imposed on the ^{4}He abundance (see also STANDARD MODEL OF PARTICLE PHYSICS). As described earlier, the ^{4}He abundance is predominantly determined by the neutron-to-proton ratio just prior to nucleosynthesis. This ratio is determined by the competition between the weak interaction rates and the universal expansion rate. The latter can be modified from its standard model prediction by the presence of 'new' particles beyond those known or expected on the basis of the standard model of particle physics. For example, additional neutrino 'flavors' ($\Delta N_\nu > 0$), or other new particles, would increase the total energy density of the universe, thus increasing the expansion rate (see equations (4) and (5)), leaving more neutrons to form more ^{4}He. For ΔN_ν sufficiently small, the predicted primordial helium abundance scales nearly linearly with ΔN_ν: $\Delta Y \approx 0.013\,\Delta N_\nu$. As a result, an upper bound to $Y_{\rm p}$ coupled with a lower bound to η (since $Y_{\rm p}$ increases with increasing baryon abundance) will lead to an upper bound to ΔN_ν and a constraint on particle physics [1].

The constraints on $N_\nu = 3 + \Delta N_\nu$ as a function of the baryon-to-photon ratio η are shown in figure 5. For 'low D, high η' there is little room for any 'extra' particles: $\Delta N_\nu \lesssim 0.3$. This would eliminate a new neutrino flavor ($\Delta N_\nu = 1$) or a new scalar particle ($\Delta N_\nu = 4/7$) provided they were massless or light ($m \ll 1$ MeV) and interacted at least as strongly as the 'ordinary' neutrinos. In contrast, much weaker constraints are found for 'high D, low η' where N_ν as large as 5 ($\Delta N_\nu \leq 2$) may be allowed (see figure 5).

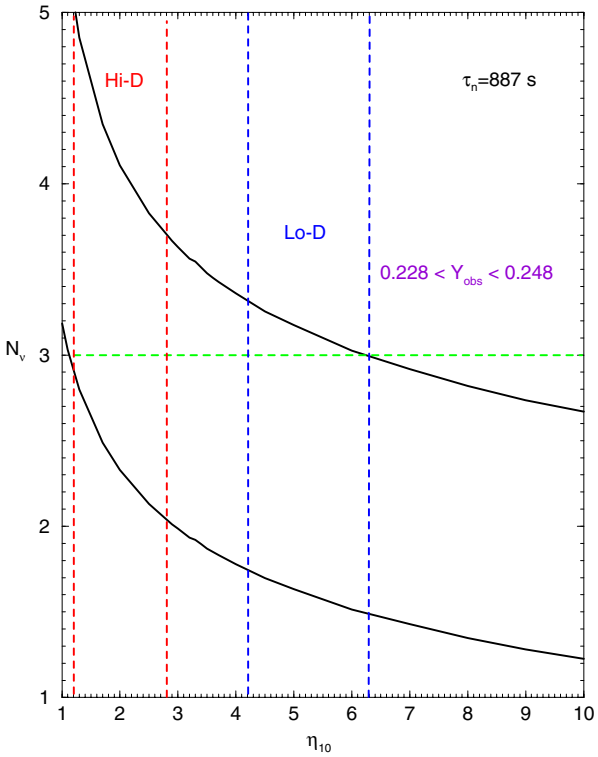

Figure 5. The number of equivalent massless neutrinos $N_\nu \equiv 3 + \Delta N_\nu$ (see equation (4)) as a function of η. The region allowed by an assumed primordial ^{4}He mass fraction in the range 0.228–0.248 lies between the two solid curves. The vertical bands bounded by the dashed lines show generous bounds on η from 'high' and 'low' deuterium.

Summary

The standard, hot, big bang cosmological model is simple (assuming isotropy, homogeneity, Newtonian–Einsteinian gravity, standard particle physics, etc) and, probably, simplistic. In broad brush it offers a remarkably successful framework for understanding observations of the present and recent universe. It may seem hubris to expect that this model could provide a realistic description of the universe during the first 20 min or so in its evolution when the temperature and density were enormously larger than today. According to the standard model, during these first 20 min the entire universe was a nuclear reactor, turning neutrons and protons into the light nuclides. This prediction presents the opportunity to use observations here and now to test the theory there and then. As described in this article, SBBN predicts observable primordial abundances for just four light nuclides, D, ^{3}He, ^{4}He and ^{7}Li, as a function of only one adjustable parameter, η, the nucleon-to-photon ratio, which is a measure of the universal baryon abundance. Even though it is currently difficult to use the extant observational data to bound the primordial abundance of ^{3}He, SBBN is still overconstrained, yielding three predicted abundances for one free parameter. Furthermore, the baryon density

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

inferred from SBBN must be consistent with that derived from observations of the present universe. Given the many possibilities that SBBN could be falsified by the empirical data, it is a remarkable success of the standard model that there is consistency between theory and observations provided that there are a few billion photons (most of them in the 2.7 K CBR) for every neutron or proton (nucleon) in the universe.

This success establishes primordial nucleosynthesis as one of the main pillars of our standard model of cosmology, providing the only probe of the physical universe during its very early evolution. Alternative theories of gravity and/or particle physics must now be tested against the impressive success of SBBN.

Light Year (l.y.)

A unit of distance measurement equal to the distance traveled by a ray of light *in vacuo* in one year. Since light travels at a speed of 299 792 458 m s^{-1} (186 282 miles s^{-1}), this distance is equivalent to 9.46×10^{12} km (i.e. 9.46 million million km) or 63 240 astronomical units. The unit is commonly used to express large distances in the universe and represents the time taken for a ray of light to cross these distances. Approximately 3.262 light-years equal one parsec.

Light-Gathering Power (Light Grasp)

A measure of the amount of light collected and brought to a focus by a telescope. The amount of light collected is proportional to the surface area of the collector (objective or primary mirror) and so is proportional to the square of the aperture. For example, a telescope with an aperture of 2 m will collect four times as much light as a telescope with an aperture of 1 m.

The pupil of the dark-adapted human eye has an aperture of about 7 mm (0.007 m). Relative to the dark-adapted human eye, a telescope of aperture D (expressed in meters), has a light grasp, $G = D^2/(0.007)^2 \approx 20\,000D^2$. For example, each of the two Keck telescopes (the largest single-mirror telescopes in the world) has an aperture of 10 m and a light grasp of $20\,000 \times (10)^2 = 2000\,000$.

See also: aperture, telescope.

Limb

The edge of a celestial body which appears as a disk, either to the naked eye or telescopically. As the body moves across the sky, the 'leading' part of the limb is termed the *preceding limb*, and the opposite, 'lagging' part the *following limb*.

Lindblad, Bertil (1895–1965)

Swedish astronomer, became director of the Stockholm Observatory. He studied the velocities of stars, including dynamics of star clusters. He realized that if the Sun and stars were in orbit around the Galaxy, it must be rotating and the stars nearer to the galactic center must be rotating faster than those away from it, just as, in the solar system, the inner planets move faster than the outer ones. Stars that were not rotating around the Galaxy must be plunging in and out through the middle of the Galaxy. Thus he showed that the Galaxy was divided into several subsystems rotating about the same axis, each subsystem having its own rotation rate and degree of flattening. The 'high-velocity' stars are actually moving slowly, not around the Galaxy but through its center, and the Sun is moving quickly through them, at right angles to their radial motion. By considering the stars in orbit, Lindblad was able to determine an approximate distance to the center of the Galaxy, estimate the galactic mass and the period of the Sun's orbit.

Lipperhey [Lippershey], Hans [Jan] (1570?–1619)

Spectacle-maker, born in Wesel (Germany), settled in Middelburg, the capital of Zeeland, Netherlands, apparently the inventor of the telescope. Lipperhey applied for a patent. A letter of the government of Zeeland to its delegation to the States General of the Netherlands, dated 25 September 1608, instructs them to help the bearer, 'who claims to have a certain device by means of which all things at a very great distance can be seen as if they were nearby, by looking through glasses, which he claims to be a new invention'. The patent application, the first record of a telescope (although not the first of an idea of a telescope), was turned down because the device could not be kept a secret. Other claimants to the invention appeared immediately afterwards in the Netherlands, including Jacob Metius of Alkmaar, and Sacharias Janssen, like Lipperhey also a spectacle-maker in Middelburg.

Lithuanian Astronomy

Lithuanian folklore, archaic calendars and terminology show that Lithuanians were interested in astronomy from ancient times. A lot of celestial bodies have names of Lithuanian origin that are not related to widely accepted ancient Greek mythology. For example, the Milky Way is named '*Pauksciu Takas*' (literally the way of birds), the constellation of the Great Bear '*Didieji Grizulo Ratai*' (literally the great pole cart), the open cluster of Pleiades '*Sietynas*' (literally the sieve), the planet Jupiter '*Indraja*', etc.

Development of modern science in Lithuania began with establishment of Vilnius University in 1579, 10 years after formation of the Polish–Lithuanian Commonwealth. The beginning of astronomical research could be related to mathematician Oswald Krüger who brought the first telescope and started the first astronomical observations in Vilnius. The book '*Illustriora theoremata et problemata mathematica ex opticis geometria astronomia* …' by Joanes Rudomina Dusiatski (1633), Krüger's student, was one of the university's first publications devoted to astronomy. In this book Galileo's telescope and observations of planets made in Vilnius were described. However, internal conflicts and foreign invasion in the middle of the 17th century ruined the country's economy and suspended further development of science. The revival in the study of science including astronomy began in the middle of the 18th century. In 1753 the Astronomical Observatory of Vilnius University was established by Thomas Zebrowski. Premises for the observatory were built atop of the three-floor university building. The golden age of astronomy began when Marcin Odlianicki Poczobut was appointed the director of Astronomical Observatory in 1764 and remained in this position for more than 40 years. He considerably enlarged the observatory and acquired a lot of new books and instruments. Among them we should mention a transit instrument, a mural quadrant, a heliometer and three achromatic refractors. Poczobut and his students were diligent and skilful observers. They obtained a lot of observational data. They observed lunar and solar eclipses, positions of asteroids, planets and comets. The most important data of that period were observations of Mercury that Jerome J. de Lalande used for calculations of Mercury's orbit. These observational programs were continued by Poczobut's successors up to the 19th century.

The Polish–Lithuanian Commonwealth declined as a political power during the 18th century. Following three partitions the old state ceased to exist in 1795. The largest part of ethnic Lithuania including Vilnius passed to Russia. The university continued its activities without much interference. However, repressions followed the uprising of 1830–1831 against the Russian regime. In 1832 Vilnius University was closed. The observatory was entrusted to the Academy of Sciences of St Petersburg and continued its activities. Eventually, positions of astronomers at the observatory were taken over by Russian astronomers, mainly from Pulkovo Observatory. The new staff were not interested in astrometric observations and made a progressive decision to go over to astrophysics, a new field of astronomy at that time. For the astrophysical research new instruments were purchased, among them were a Merz spectroscope, a visual Schwerd's photometer and a photoheliograph. The first successful photographs of the Sun obtained in 1868 stimulated further observations of the Sun and monitoring of the solar activity. In addition, spectroscopic studies of the Sun and photometric observations of stars were carried out. Unfortunately, in 1876 a fire broke out at the observatory, causing heavy damage. The observatory did not receive means for refurbishment and five years later it was closed. The library and instruments were transferred to Pulkovo Observatory and other institutions of Russia. Revival of astronomy was possible only in the period between World Wars I and II. Then the larger part of ethnic Lithuania became independent with a temporary capital Kaunas. Poland occupied the smaller part of it including the old capital Vilnius. By 1920 Vilnius University was reopened and the Astronomical Observatory began its activities. In the following decade new observatory buildings at the outskirts of Vilnius were built and new instruments were purchased. Among these were two 15 cm Zeiss astrographs and a 48 cm telescope. The research was mainly concentrated on investigation of variable stars and on stellar statistics.

An astronomical observatory was established in Kaunas University in 1928. It was equipped with several small telescopes. The observatory planned to build a large telescope and purchased a 63 cm mirror for that purpose. However, the beginning of World War II and subsequent political alterations discontinued activities of the observatory. By the beginning of World War II Lithuania was incorporated into the Soviet Union until recovery of its independence in 1990.

After World War II activities of astronomers resumed at Vilnius University. Eventually, a new astronomical center at the Institute of Physics and Mathematics of the Academy of Sciences emerged. The postwar generation of astronomers concentrated on applications of stellar photometry for investigation of physical properties of stars and galactic structure. They studied the properties of the UBV photometric system and made some proposals for its revision. Later, they devised a new seven-color photometric system under Vytautas Straizys. The colors and the mean wavelengths of the Vilnius photometric system are as follows: U, 345 nm; P, 374 nm; X, 405 nm; Y, 466 nm; Z, 516 nm; V, 544 nm; S, 655 nm. This system enables temperatures, luminosities, metallicities and reddenings of various kinds of stars to be derived.

Dirac House, Temple Back, Bristol, BS21 6BE, UK

Recently, the Vilnius photometric system was combined with colors of the Stromgren system and a new Stromvil photometric system proposed. In the period 1968–1980 two observing stations were built, one at Moletai (Lithuania) and another at Maidanak Mountain (Central Asia, Uzbekistan). Moletai was equipped with 1.65 m and 63 cm reflectors and a 35 cm Maksutov telescope. At the Maidanak observing site 1 m and 48 cm telescopes were installed . The telescopes were mainly used for stellar photometry. After the disintegration of the Soviet Union and re-establishment of independent Lithuania the telescopes of the Maidanak Observatory were taken over by the Academy of Science of Uzbekistan. At the present time astronomical research is carried out in two universities, Vilnius University and Vilnius Pedagogical University, as well as in two institutes, the Institute of Theoretical Physics and Astronomy and the Institute of Physics. The main research fields are physical properties of stars and interstellar matter, the structure and evolution of the galaxy, structure and evolution of stellar systems, and design of astronomical instrumentation. The *Bulletin of Vilnius Astronomical Observatory* was published in 1957–1992. The international quarterly journal *Baltic Astronomy* has been published since 1992.

Little Dumbbell Nebula (M76, NGC 650–51)

A planetary nebula in the constellation Perseus, position RA $01^{h}\ 42.3^{m}$, dec. $+51^{\circ}\ 34'$. At eleventh magnitude and measuring $2'$ by $1'$ it looks something like a miniature version of the Dumbbell Nebula (M27). Each of the two lobes has a separate NGC number.

Liverpool John Moores University Astrophysics Research Institute

Astrophysics at Liverpool John Moores University continues a tradition of astronomical endeavor on Merseyside that stretches back nearly 400 years. The Astrophysics Research Unit (ARI) is now located in a new, purpose-built building on the Mersey riverfront. Its primary objective is to undertake world-class research, allied to innovative teaching and wider educational projects. It is supported by University, Research Council and European funds and is the home of the Liverpool Telescope (LT) project.

The LT is the world's largest robotic telescope and will be fully operational as a UK national research facility in the Canaries in 2000. It has been designed and constructed by the university-owned company, Telescope Technologies Ltd, who are sited next to the ARI, and who are currently building several other large telescopes. The ARI runs a unique joint degree program in astrophysics with the University of Liverpool; a pioneering distance-learning course (with students all over the world), and a schools' program in science, technology and IT focused on access to the Liverpool Telescope.

Lobate Scarp

A long, sinuous cliff-like feature consisting of a series of connected lobes. They are found chiefly on Mercury, where they are interpreted as thrust faults caused by compressive forces. They vary from 20 to 500 km in length and from a few hundred meters to 2 km in height. Their planet-wide distribution is taken as evidence of a global shrinking early in Mercury's history when the mantle and core cooled and contracted, and the crust 'puckered'. One of the longest is Discovery Rupes, which crosses craters; others are found in the Caloris Basin. The global contraction must therefore have happened after the era of major cratering, which ended about 3.9 billion years ago.

Local Group

Not long after EDWIN HUBBLE established that galaxies are 'island universes' similar to our home galaxy, the MILKY WAY, he realized that a few of these external galaxies are considerably closer to us than any others. In 1936 he first coined the term 'Local Group' in his famous book *The Realm of the Nebulae* to identify our nearest galactic neighbors. More than 60 yr later, the galaxies of the Local Group remain particularly important to astronomers because their proximity allows us to obtain our most detailed views of the properties of normal galaxies beyond our own. These nearby systems also provide our clearest views of how galaxies interact with one another in the relatively small volume of space of the Local Group.

The brightest members of the Local Group are so close to us that on a clear, dark night away from city lights it is possible to see them with the unaided eye: in the southern hemisphere the LARGE MAGELLANIC CLOUD (LMC) and SMALL MAGELLANIC CLOUD (SMC) shine brightly, while in the north the ANDROMEDA and TRIANGULUM GALAXY can be seen as faint smudges of light in the sky. These two galaxies are, in fact, the most distant objects visible with the naked eye. From both hemispheres, the gossamer glow of the Milky Way reveals the presence of billions of stars spread throughout the thin disk of our home galaxy. These five galaxies constitute the most luminous and massive members of the Local Group.

Although the existence, if not the true nature, of the five naked-eye Local Group galaxies and the Milky Way has been known to humans since antiquity, the first member identified telescopically was Messier 32 (more typically referred to as M32) by G-J Le Gentil in 1749. Since then, astronomers have steadily identified additional members of the Local Group. By the time Hubble first introduced the concept of the Local Group in 1936, he was able to list 11 galaxies that he considered to be members of the group. At present (1999), 43 galaxies can be catalogued as probable members of the Local Group; these systems are listed in table 1 along with the dates of discovery for each. Remarkably, more Local Group members have been found in the past 30 yr than in all previous human history. Also, the era of discovery is almost certainly not over as future surveys uncover more members or as new nearby galaxies are found serendipitously.

Why are the galaxies of the Local Group so difficult to identify? The principal reason is that, apart from our Milky Way Galaxy and the large Andromeda and Triangulum galaxies (known also as M31 and M33, respectively), the known members of the Local Group are DWARF GALAXIES. By definition, these systems have low intrinsic luminosities. They usually also exhibit very low surface brightness (see LOW SURFACE BRIGHTNESSES GALAXIES). This property is a measure of how spread out the galaxy's light is on the sky. In the case of nearly every dwarf galaxy member of the Local Group, the surface brightnesses are lower than that of the night sky, lending them a ghostly appearance and making them very difficult to detect, even at close range[1].

Much of the recent success in finding new Local Group members is due to the availability of the many large-scale photographic surveys of the sky carried out since the seminal Palomar Sky Survey of the 1950s. Soon after these surveys were begun, visual searches of the photographic plates identified new nearby galaxies. Starting in the 1970s, automated measurements and analyses of the plates from these surveys helped uncover nearly all of the most recently discovered Local Group members. However, even the most complete optical survey cannot find all of the galaxies in the sky. For example, searches for galaxies near the bright band of the Milky Way itself are severely hindered by the high stellar density in this part of the sky and by the clouds of gas and dust within the plane of our Galaxy. This INTERSTELLAR MATTER effectively blocks all optical light from distant objects, making it impossible to find galaxies lurking in the background. Ongoing and planned surveys in the infrared and radio wavelengths can penetrate the haze of the Milky Way by detecting radiation that is unaffected by dust obscuration. These searches are almost certain to reveal several new Local Group members in coming years.

Another complication in producing a complete census of the Local Group is the uncertainty involved with defining the group's boundary. The best way to establish this is to determine which local galaxies are gravitationally bound to one another. Since M31 and the Milky Way dominate the mass of all probable Local Group members, this process requires a good estimate of the masses of these two giant galaxies (see below). In addition, we need accurate information on the distances and motions of individual candidate Local Group galaxies to determine whether they are physically bound to the M31–Milky Way system. Table 1 lists the 43 galaxies that appear to be likely members of the Local Group based on this approach.

Although well defined, this method of identifying and counting members of the Local Group is highly uncertain. For example, apart from a few of the nearest galaxies, we cannot measure the PROPER MOTION—the angular movement across the sky—of external galaxies. A galaxy that may be moving towards or away from us at a moderate speed may be moving very rapidly across our line of sight. Thus, some of the galaxies in the table that we believe are bound to the Local Group may actually only be 'passing through the neighborhood'. A second problem is that distances to local galaxies are notoriously difficult to determine reliably. Methods that work for the Magellanic Clouds may not be applicable to other nearby galaxies, and vice

[1] Unlike the apparent brightness of a galaxy, the surface brightness of an extended object does not change as a function of distance—at least for distances up to a few hundred million light-years. This makes low-surface-brightness galaxies difficult to detect anywhere. Consequently, a very large number of low-surface-brightness galaxies may still remain hidden throughout the universe, enough possibly to fundamentally change our views of the distribution and numbers of galaxies in the universe.

versa. It is quite common that galaxies once believed to be Local Group members are later removed from the list of members as we refine our estimates of their distances and motions. Indeed, two of the galaxies Hubble first proposed to be Local Group members are now known to be located much further away. Thus we can not only expect additions to the table of Local Group members as new galaxies are discovered but also subtractions from the list as we learn that some of the galaxies are not members after all.

Global properties of the galaxies of the Local Group

The individual galaxies of the Local Group span a large range of basic properties. The luminosities of Local Group galaxies range from a minimum of about 250 000 times the luminosity of the SUN, to a maximum of more than 20 billion times the luminosity of the Sun, a range of a factor of 75 000. It is also clear that the galaxies of the Local Group span a very large range in size even though their extreme dimensions are impossible to determine precisely. The smallest systems in the Local Group are approximately 1000 ly in diameter, while the luminous parts of the giant galaxies M31 and the Milky Way span over 100 000 ly from end to end. This range is comparable with the size range exhibited by mammals, from the tiny bumblebee bat to the blue whale. Figure 1 illustrates the relative sizes of the visible portions of most of the Local Group galaxies.

Virtually every major galaxy type is represented in the Local Group. M31, the Milky Way and M33 are all examples of SPIRAL GALAXIES, but each represents a slightly different subclass of this family of galaxies. M31, for example, exhibits a prominent central bulge and well-defined spiral arms throughout the thin disk of the galaxy; it is classified as an Sb galaxy (see GALAXIES: CLASSIFICATION). M33 has a very weak, possibly non-existent central bulge and very poorly defined spiral arms; it is an Sc galaxy.

Figure 1. A family portrait of many of the members of the Local Group. The galaxies are shown to scale and to roughly the correct range of relative brightness. The Milky Way is shown as it may appear to a viewer located outside the galaxy. This montage was produced by Bruno Binggeli of the University of Basel.

Although it is clear that the Milky Way is a spiral galaxy—the thin structure of the Milky Way and the existence of a concentration of stars and GLOBULAR CLUSTERS towards the constellation Sagittarius all confirm this classification—the specific spiral subtype is extremely difficult to determine reliably from our unfavorable vantage point inside the Galaxy. Various indirect indicators suggest that our Galaxy can be classified as an Sbc galaxy, intermediate between the properties described for M31 and M33. Some recent studies at radio, infrared and optical wavelengths also suggest that our Galaxy contains an elongated central bar composed of old, metal-rich stars. If true, then the Milky Way is an example of a BARRED SPIRAL GALAXY, and its specific subtype is SBbc, where the upper-case 'B' denotes a barred system. All three galaxies are typically considered 'giant' spirals, despite the fact that M33 is only about 10% as luminous or massive as M31. By comparison, our Galaxy is about half as luminous and massive as M31.

All the remaining galaxies of the Local Group are dwarf systems of various types. The galaxies that exhibit the most variation in appearance and in their global properties are the DWARF IRREGULAR GALAXIES. The most massive example of this type of galaxy in the Local Group is the LMC, one of the satellites of the Milky Way and the second closest external galaxy to the Sun. The LMC is a massive dwarf, and its global properties place it near the ill-defined boundary separating dwarf irregular galaxies from small spirals. Careful studies reveal features in the LMC normally found in spiral galaxies, such as a central bar-like concentration of older stars, and some evidence of indistinct spiral arms. The LMC's companion, the SMC, is a true irregular with little sign of large-scale structure. The remaining irregular galaxies of the Local Group are identified in the table. All of these systems are substantially smaller and less luminous than the LMC.

The principal reason that dIrr galaxies appear to have such chaotic structures is that they typically form stars in small clumps called associations embedded within the galaxies. Because young stars are typically very luminous, they are often the most prominent stars seen in optical images of these types of dwarf galaxies. If the star-forming regions are irregularly distributed—and they usually are—they give a strong impression that the entire galaxy has a highly distorted, chaotic overall structure. Figure 2 illustrates the appearance of a dwarf irregular galaxy Sextans A, both from a ground-based image and from an image taken with the HUBBLE SPACE TELESCOPE. The luminous young blue and red stars are distributed non-uniformly, lending this galaxy its highly disorganized appearance.

This apparent lack of large-scale organization in dIrr galaxies is somewhat of an illusion produced by the luminous young stars that generally make up a minority of the total stellar population of such galaxies. Observations in the red and infrared are most sensitive to the light output of the dominant population of old and middle-aged stars in these galaxies. When astronomers try to determine the distribution of these oldest stars, even the

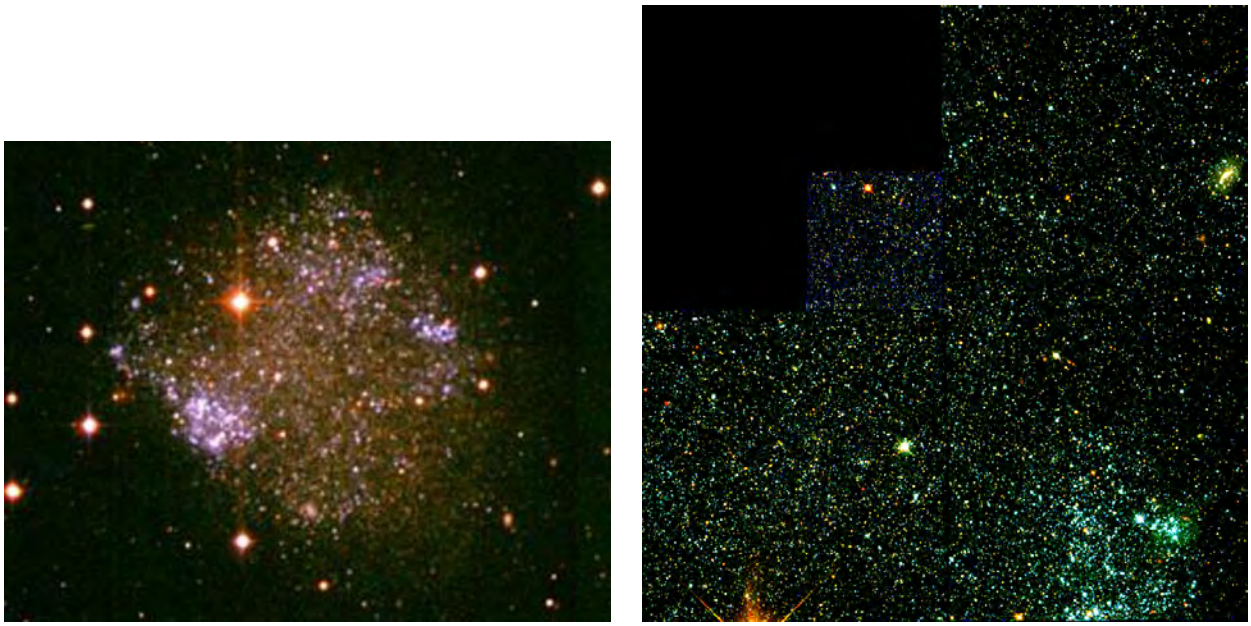

Figure 2. (Left panel) A ground-based color image of the Local Group irregular galaxy Sextans A. The entire central region of the galaxy is included. Notice how the bright clumps in the body of the galaxy are dominated by blue–white stars. Such stars are very hot and young objects indicating that these clumps are regions of relatively recent star formation in the galaxy. This image was taken by Diedre Hunter of Lowell Observatory. **This figure is reproduced as Color Plate 9.** (Right panel) An image of the central region of Sextans A obtained with the Hubble Space Telescope. In this image the individual stars in the clump located to the left of the galaxy's center in the left-hand panel are now easily apparent. Note too how red stars are more common away away from the bright clump of blue stars; these redder stars trace star formation in the galaxy long ago and show clearly that star formation has gone on over an extended period in Sextans A. This complex spatial and temporal star formation history is common for most of the dwarfs of the Local Group, especially the irregular galaxies. The HST photograph was provided by Robbie Dohm-Palmer of the University of Minnesota and the University of Michigan. **This figure is reproduced as Color Plate 10.**

most irregular dwarfs exhibit a much smoother, more symmetric appearance. An analogy is the surface of a pot of slowly boiling soup: although bubbles erupt at different locations at different times, the overall distribution of the soup is relatively uniform. The active star-forming regions of irregulars correspond to the bubbles: very prominent when active, but short lived and all interspersed in a more uniform medium.

With the striking exception of the Magellanic Clouds, the dIrr galaxies of the Local Group tend to be found far from the two large galaxies (M31 and the Milky Way) of the Local Group. A few of the least luminous dwarf irregulars are also among the most metal-poor galaxies known. Because stars produce heavy elements which they then eject back into the interstellar medium at the ends of their lives, the low abundances of such elements in the smaller dwarfs suggest that these galaxies are relatively pristine, unevolved systems. These galaxies may be forming stars in large quantities for the first time in their lives. As such, these galaxies are invaluable 'living fossils' that can tell us of the properties of gas and stars in the early universe.

One particularly interesting Local Group irregular galaxy is IC 10. This galaxy is forming stars at an unsustainably rapid rate. If it were to continue it would soon exhaust its raw materials for making stars (gas and dust) in only a few million years. The implication is that unless it started out with an astoundingly large reservoir of gas from which to form stars, IC 10 has probably been caught during a particularly active—but short-lived—phase in its star-formation history. Such galaxies that appear to form stars at unsustainably high rates are known as STARBURST GALAXIES. IC 10 is probably the closest example of a true starburst galaxy, although one active region of star formation in the LMC—the 30 Doradus Region—exhibits similar characteristics on a subgalactic scale.

The remaining dwarfs of the Local Group are ellipsoidal systems. These galaxies are characterized by a roughly circular or elliptical outline on the sky, and by a smooth, centrally concentrated distribution of light. One of these, M32, is considered to be an example of a true DWARF ELLIPTICAL GALAXY. As such, it represents the low-luminosity end of the very large family of elliptical galaxies which includes some of the largest, most luminous and most massive individual galaxies known. M32 is also noteworthy because it appears to harbor a massive BLACK HOLE in its extremely bright nucleus, it may be a unique local example of a galaxy with no ancient stars and, as a companion of M31, it shows distortions that indicate a strong gravitational interaction with its massive parent.

The remaining ellipsoidal Local Group galaxies are

known as DWARF SPHEROIDAL GALAXIES (or dSph galaxies). About half of all galaxies in the Local Group are of this type and they are apparently similarly common in other groups and clusters. Consequently, these dim, unassuming galaxies probably represent the most common type of galaxy in the entire universe. Within the Local Group, dSph galaxies are typically found in the company of a larger parent galaxy. For example, of the 13 close companions of the Milky Way, nine are dSph satellites. Virtually all the remaining dSph galaxies of the Local Group are found near M31. The most luminous dSph galaxy, NGC205, is a highly distorted companion of M31 (figure 3). The two lowest-luminosity galaxies known are dSph companions of the Milky Way: the Draco and Ursa Minor systems. These galaxies emit less light than some individual globular clusters—massive, compact star clusters typically found within extended halos surrounding elliptical, spiral and larger dwarf galaxies (see HALO, GALACTIC). Nevertheless, the large dimensions and large masses (most in the form of matter that we cannot see directly) of galaxies such as Draco and Ursa Minor distinguish them from the more compact clusters.

Five of the dwarf galaxies of the Local Group are difficult to classify as ellipsoidal or irregular systems because they exhibit some of the properties of both. These 'transition' galaxies may represent the late stages of star-formation episodes in dwarf irregulars fortuitously caught during the period when the youngest stars begin to fade from prominence. This picture is consistent with the star-formation histories we measure for transition systems and with the growing evidence that dSph and dIrr galaxies have undergone complicated star-formation histories over the entire lifetime of the universe. A few hundred million years after periods of active star formation, a dSph galaxy that may initially have looked like a dIrr system could become a transition galaxy. This intimate relation between dIrr and dSph galaxies in which 'transition' systems act as a 'missing' evolutionary link remains controversial. Nonetheless, there is little doubt that some dSph galaxies looked a lot like low-luminosity dIrr systems at some point(s) in the past.

Galaxies are not the only inhabitants of intergalactic space within the Local Group. There is growing evidence of the existence of isolated clouds of gas, usually in the form of neutral hydrogen, distributed throughout the group. This material may represent gas expelled from other galaxies or may correspond to primordial matter that has yet to collapse into small stellar systems such as globular clusters or dwarf galaxies. Some remote globular star clusters could plausibly be 'free-floating' members of the Local Group that were ejected from their parent galaxies during past interactions of individual galaxies within the group.

One prominent class of normal galaxy is not found within the Local Group: giant elliptical galaxies. This is not entirely surprising; since large ellipticals are relatively rare in the local universe, we would have been 'lucky' to find one closeby. Moreover, giant ellipticals tend to be found in regions with a high density of galaxies, a manifestation of the so-called GALAXY MORPHOLOGY–DENSITY RELATION. Because the Local Group is a loose, low-density collection of galaxies, it would have been unusual—although not impossible—for it to contain one or more big elliptical galaxies. The nearest giant elliptical galaxy to us is probably MAFFEI 1. The slightly more distant Centaurus A (NGC 5128) is somewhat easier to study because it is not located so close to the Milky Way in the sky and suffers far less obscuration by interstellar dust in the plane of our Galaxy.

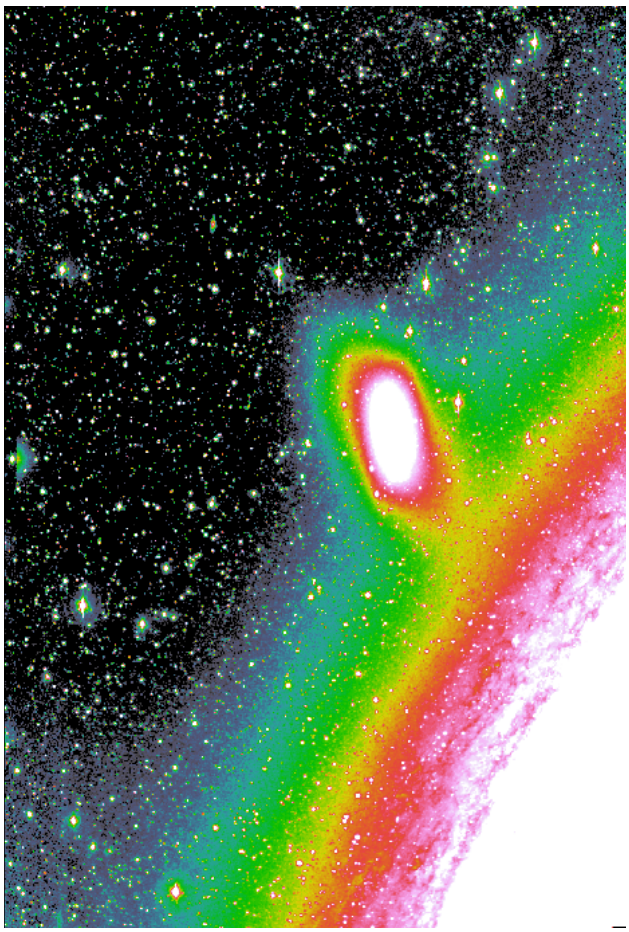

Figure 3. An image of NGC 205, a dwarf spheroidal companion of M31. The bright galaxy to the lower right of the figure is M31 itself. Note how close to the larger galaxy NGC 205 appears to be and how the outer extent of NGC 205 appears distorted from the smooth elliptical shape apparent near the galaxy core. This distortion is due to the strong tides that are induced in NGC 205 during its close passage to its much larger parent, M31. M32 and the Sagittarius dwarf also show evidence of tidal disruption by M31 and the Milky Way, respectively. The Magellanic Clouds show clear evidence of tidal distortion due to mutual interactions over the past few billion years. This image was obtained by Paul Harding, Heather Morrison and Anne Fry of Case Western Reserve University.

The motions of galaxies within the Local Group

The motions of galaxies in the Local Group appear to violate HUBBLE'S LAW that the universe is uniformly expanding. The reason for this has to do with the definition of the Local Group as the collection of nearby galaxies that are gravitationally bound to one another. Just as the planets of the solar system do not appear to be expanding away from us because they are bound to the Sun, the mutual attraction of galaxies within the Local Group has overcome the universal expansion in our immediate neighborhood. The most striking example of this is M31, which is currently approaching our galaxy at nearly 50 km s^{-1}: if on a true collision course, the two galaxies will meet in about 8–10 billion years. More likely, M31 and the Milky Way make up a binary system in which the two galaxies orbit their common center of gravity. Inevitably, tidal effects will cause the two galaxies to merge into one giant system at some time in the distant future. Many of the other galaxies of the Local Group also exhibit motions towards us, signifying that they too are either in orbit about the Milky Way or currently moving along orbits about M31 or other Local Group galaxies that cause them to move towards us at the present time. In all of these cases, the orbital motions are larger than the universal expansion velocities we would expect to measure for such nearby galaxies based on Hubble's law.

The mutual attraction of M31 and the Milky Way can be used to estimate the mass of the Local Group. Much as a ball thrown in the air first rises, stops and then falls, M31 and the Milky Way are now falling towards each other after their initial movement apart after the BIG BANG. If one measures the relative velocities and locations of the two galaxies and one estimates how long it has been since they were together—essentially the age of the universe estimated from the Hubble constant or from the ages of the oldest stars—it is possible to estimate the combined mass of M31 and the Milky Way. This sort of analysis was first carried out by F D Kahn and L Woltjer in 1959. Modern applications of this technique reveal that the combined mass of M31 and the Milky Way is in the range between 500 billion and 2 trillion times the mass of the Sun. Because virtually all the matter of the Local Group is located in these two giant spiral galaxies, this is also our best estimate of the total mass of the group.

As massive as the Local Group is, the total light output of all of the galaxies in the group M31 and the Milky Way is equivalent to 'only' 30 billion times the luminosity of the Sun. This is unusual because for normal stars the ratio of their mass (in units of the mass of Sun, or 2×10^{30} kg) and their luminosity (also in units of the luminosity of the Sun, or 4×10^{26} W) is around 1. For the Local Group the ratio is much higher, approximately 50. This suggests that the group is dominated by 'DARK MATTER' which contributes to the local gravitational field but remains invisible at any wavelength of ELECTROMAGNETIC RADIATION. The large mass-to-light ratio of the Local Group implies that only 2–5% of the total matter in the group is visible to us through emitted or reflected radiation.

We can also measure the masses of Local Group galaxies individually by determining the range of velocities of individual stars and gas clouds that orbit within individual systems. So long as Newton's law of gravity remains valid over the physical scales of the galaxies, astronomers find that Local Group galaxies typically exhibit mass-to-light ratios in the range 3–100 (see table 1). Thus, the dark matter within the Local Group is not spread out uniformly throughout the group, but is instead concentrated about the individual galaxies we detect optically. This suggests that possibility that the Local Group may contain some nearby examples of 'dark' galaxies consisting of only dark matter with no luminous material. No such systems have been detected yet. The dwarf galaxies of the Local Group do offer one important clue about the nature of dark matter. Certain types of dark matter that have been postulated in the past—in particular NEUTRINOS—cannot account for the surprisingly high mass densities required to account for the total masses of these small galaxies.

The distribution of galaxies within the Local Group

Figure 4 shows a stereoscopic picture of the Local Group. It is quite clear from this three-dimensional image of the Local Group that the group's volume is not uniformly filled with galaxies. Instead, most of the galaxies appear to congregate into three clumps; the remaining galaxies are spread out into a larger 'cloud' of galaxies that occupies a large fraction of the total volume of the Local Group. The smaller 'subgroups' correspond to M31 and its satellites, the Milky Way and its companions, and the 'NGC3109 subgroup' comprising five small galaxies that are well separated from M31 and the Milky Way. The galaxies of the more extended cloud—the so-called 'Local Group Cloud'—are not obviously associated with any single larger galaxy. Table 1 lists the subgroup with which each Local Group galaxy is most likely associated.

In general, each subgroup corresponds to a set of gravitationally bound galaxies. The 13 satellites of the Milky Way, for example, are all likely to be in orbit about our Galaxy while M31 maintains a similar stable of small companion galaxies. This situation is analogous to the moons that orbit individual planets of the Solar System: although Jupiter and Saturn orbit the Sun, both planets possess their own large families of bound satellites. In the case of the Local Group, the subgroups are weakly bound together, and there is evidence that some satellites may be occasionally 'swapped' from one subgroup to another. For example, some models of the dynamical evolution of the Local Group suggest that the Magellanic Clouds and perhaps the Leo I dSph galaxy may have first formed near M31, but are now satellites of our Galaxy.

Some Local Group galaxies show unmistakable signs of strong mutual gravitational interactions. As noted above, the Milky Way and M31 have overcome the initial expansion and are now falling in towards one another. The close companions of M31—NGC 205 and M32—both

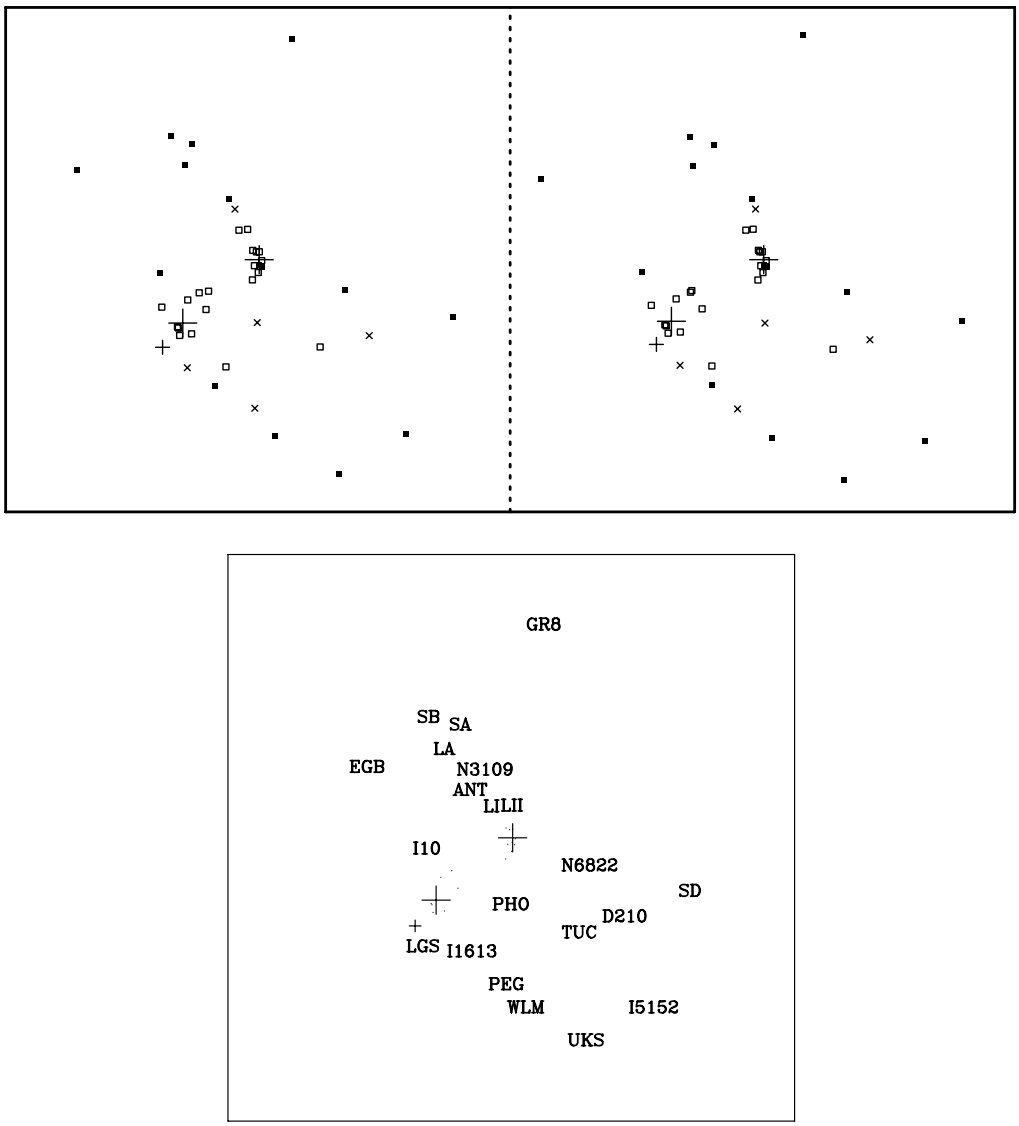

Figure 4. (Top panel) A stereo map of the Local Group showing its approximate three-dimensional structure. The view is from a point located about 7 million ly directly in front of the Sun's current motion about the center of the Milky Way. The large cross near the center of each panel denotes the position of the Milky Way, while the large off-center cross is M31. The smaller cross represents M33. The open squares show the locations of the dwarf ellipticals and dwarf spheroidal galaxies; the solid squares denote the dwarf irregulars; and the small ×s are the transition galaxies. The MW, M31 and NGC 3109 groups are easily visible; the latter is on the 'far' side of the figure. The large diffuse 'bubble' of galaxies extending to the lower right and towards the viewer is the Local Group Cloud. (Lower panel) A guide to the identities of individual galaxies in the stereo image. The systems are denoted with abbreviations that should—in conjunction with the names listed in table 1—uniquely define each galaxy. The galaxies closest to M31 and the Milky Way are not identified in order to minimize confusion in those crowded regions of the figure.

show global distortions that may be due to strong tidal effects induced by their close passage to their parent galaxy (figure 3 shows the distortions induced in NGC 205 by its close passage by M31). The Magellanic Clouds reveal considerable evidence that they too have interacted in the past. For example, the MAGELLANIC STREAM is a long arc of neutral gas that was probably ejected from one or both of the Clouds as they passed close to one another and passed the Milky Way. Because the SMC is the least massive component of the interacting pair, it has suffered the most. One clear sign of this is the fact that the SMC is elongated significantly along our line of sight, resembling a cigar whose long axis is roughly pointed towards us. This elongation reflects the stretching of the galaxy as it is literally pulled apart by its abusive neighbor. Detailed models of the dynamical evolution of the Magellanic Clouds indicate that they will both fall into the Milky Way in the next few billion years. Although the Clouds will be

Dirac House, Temple Back, Bristol, BS1 6BE, UK

completely disrupted in the process, even the much-larger Milky Way will be affected as its disk is puffed up by the energy injected by the infalling dwarfs.

Perhaps the most spectacular example of an interaction within the Local Group involves the Sagittarius dSph galaxy. Discovered only in 1994, the SAGITTARIUS DWARF GALAXY is now known to be the closest galaxy to the Milky Way. Sadly for Sagittarius, this is too close, and the dwarf is being severely torn apart by the gravitational tidal forces exerted on it by our much more massive Galaxy. A clear indication that this process has already begun is the fact that Sagittarius has been stretched along a long arc that currently is known to extend nearly all of the way around the sky. Like the Magellanic Clouds, Sagittarius does not have long to live as a separate galaxy before it too is completely disrupted and merges into the main body of the Milky Way.

Cosmological implications of the Local Group

Although most studies of the origin of the universe focus on radiation coming from extremely distant galaxies, the Local Group also plays a critical role in cosmological studies. For example, with the advent of large ground-based and space-based telescopes and the use of high-sensitivity electronic detectors, it has become possible to measure the complete fossil record of star formation in many of the galaxies of the Local Group. These investigations provide a critical point of comparison with studies aimed at understanding how galaxies formed in the first place by studying objects detectable at the edge of the visible universe. So far, observations of Local Group systems reveal that normal galaxies have formed stars in unexpectedly complex and varied ways. Some nearby dwarf spheroidal galaxies are composed almost entirely of ancient stars formed soon after the big bang, but most of these galaxies formed large numbers of stars over long periods of time extending as recently as the past few hundred million years. The dwarf irregulars continue to form stars today, in some cases perhaps for the first time. Astronomers are just now beginning to try to reconcile these detailed observations of Local Group galaxies with studies of larger numbers of extremely remote galaxies.

The Local Group also offers insights into the question of whether small galaxies have merged over time to form larger systems such as M31, the Milky Way or the Magellanic Clouds. Some of the mergers can be studied today such as the disruption of the Sagittarius dwarf and the interactions of the Magellanic Clouds and our Galaxy described above. However, most mergers that led to the formation of larger galaxies must have occurred long ago when the universe was still quite young; we are only now beginning to understand how to disentangle evidence of these past encounters within our own Galaxy. The merger histories of Local Group galaxies will eventually shed new light on the conditions of the early universe and on the nature of the dark matter that helped drive the formation of galaxies in the first place.

On an even larger scale, the Local Group itself seems to interact significantly with other nearby groups of galaxies. One of these, the Sculptor Group, appears to be strongly elongated along a line projecting back to the Local Group. Because our group is considerably more massive, it is probable that the gravitational force of the Local Group has significantly distorted the Sculptor Group. One result of this interaction is the lack of a clear boundary between the Sculptor Group and our own. Some galaxies traditionally associated with Sculptor are occasionally catalogued with the Local Group and vice versa. Unlike the Local Group, Sculptor lacks any giant galaxies, but does contain a number of lower-luminosity spirals and many dwarf galaxies. On roughly the opposite side of the sky the M81–Maffei Group represents another nearby concentration of galaxies that may have a significant effect on the evolution and internal motions of the Local Group. Unlike the Sculptor Group, the M81–Maffei Group contains some giant galaxies, including the large spiral M81 and the elliptical galaxy Maffei 1. As with the Sculptor Group, some of the galaxies assigned to the M81–Maffei Group have been considered at times to be Local Group members and vice versa. On top of the interactions with neighboring groups, the Local Group is also 'falling' into the nearby VIRGO CLUSTER of galaxies. The attempt to understand the details and implications of these local interactions and large scale motions remains a very active field of modern research.

Lockyer, Joseph Norman (1836–1920)

Civil servant, professor at the Solar Physics Observatory, Kensington (later moved to Cambridge), born in Rugby, Warwickshire, England. Attracted to astronomy by an observation of the annular solar eclipse of 1858, erected an observatory at his home in Hampstead, observed Mars. Lockyer showed spectroscopically that phenomena seen during a total eclipse (such as the prominences) could be seen in daytime on the Sun and were not lunar phenomena. These conclusions were simultaneous with conclusions by JULES JANSSEN, and were reported to the same meeting of the Académie des Sciences, which offered the pair a medal (in contrast to the squabble over precedence in Neptune's discovery, *see* JOHN ADAMS). Lockyer identified all the emissions in the solar spectrum except for one spectral line near the sodium emission. He suggested that the line was due to a new element which he named 'helium' after the Greek, helios, for Sun. Helium was isolated on the Earth 25 years later by William Ramsay (1895), and Lockyer was knighted. Lockyer founded *Nature*, a new journal dedicated to the natural sciences and continuing to this day. While on holiday in Greece he noticed that temples were oriented east–west and connected this alignment to sunrise at their foundation. He extended this thought to temples in Egypt and found an alignment corresponding to midsummer sunset in the main axis of the Great Temple of Amon-Re at Karnak. Other alignments were apparently connected with Sirius. At Stonehenge he hypothesized that the midsummer Sun rose originally over Heel stone, and calculated back to determine when it would have done so, to establish the date when Stonehenge was built. Although his work is regarded as incorrect, Lockyer's belief in the astronomical purposes of Stonehenge and other stone circles was the impetus behind this kind of research in the twentieth century (see GERALD HAWKINS) and he was thus the founder of astroarchaeology. He built the Hill Observatory, later the *Norman Lockyer Observatory* (Sidmouth, Devon), just before his death; it is still operational, with an active society of astronomers.

Lohrmann, Wilhelm Gotthelf (1796–1840)

Surveyor and amateur astronomer, born in Dresden, he was the second selenographer (after TOBIAS MAYER) to make and publish a lunar map based on quantitative measurements and geometric calculations, rather than merging eye-sketches. Lohmann's map was based on a diameter of the Moon of about a meter, over five times the diameter of Mayer's. He was helped and encouraged by CARL GAUSS and J ENCKE. Publication of the atlas (*Topography of the Visible Surface of the Moon*), including over 7000 craters, started in 1824 but was a protracted process, slowed by Lohrmann's failing eyesight, and not completed (supervised by Julius Schmidt) until 38 years after his death.

Long-period Comet

A comet whose period is more than 200 years. Comets with periods of less than 200 years are termed *periodic comets* or *short-period comets*. Long-period comets are also 'periodic', but a comet can be incontrovertibly classified as periodic only when it has been observed on at least two returns; the choice of 200 years as a cut-off is traditional, but arbitrary. It happens that no comet calculated to have a period of over 200 years has yet been observed to return since its discovery. The first to do so will be Comet Peters (C/1857 O1), expected to return in 2092. In the system of cometary designations introduced in 1995, 'C/' is the prefix assigned to long-period comets.

Long-period comets show a much greater spread of orbital inclinations than do short-period comets. Many have very long periods indeed, and some appear to be on open, hyperbolic orbits. However, when the apparent orbits of long-period comets round the Sun (osculating heliocentric orbits) are referred instead to the center of mass of the solar system (to yield barycentric orbits), they are all found to be elliptical, once allowance is made for planetary perturbations and non-gravitational forces. About one-third of all long-period comets are found to have periods close to a million years, corresponding to aphelia of rather less than 50 000 AU, while the periods of the other two-thirds are fairly evenly spread between a million years and 200 years. The million-year peak points to the origin of these comets in the Oort Cloud.

See also: comets, non-gravitational force, Oort Cloud, short-period comet, solar system: nomenclature.

Lovell, Alfred Charles Bernard [Sir Bernard] (1913–)

Physicist and astronomer, born in Oldland Common, Gloucestershire, England. Worked on cosmic rays at Manchester, researched radar in the Second World War, and afterwards with J S HEY procured an ex-army mobile radar unit used to detect V-2 rockets and attempted to detect cosmic ray showers with it. Interference from the electric trams at Manchester displaced the work to the university's botanical research station at Jodrell Bank (now the Nuffield Radio Astronomy Laboratories), where he found that echoes came from the ionized trails of meteors, particularly the Giacobinid display of October 1946. With JA Clegg, he laboriously built a 218 foot diameter wire-bowl parabolic transit telescope, used by Hanbury Brown and Hazard to detect M31. This showed the advantage of a large fully steerable telescope, and Lovell became the driving force behind the construction of the 250 foot diameter Mark 1 Jodrell Bank Telescope, completed by engineer HC Husband in 1957. Subject to painful allegations about its cost-overruns during its construction, the Mark 1 telescope was thrust into public view and rescued from ignominy that year by receiving signals from Sputnik, and American space vehicles. Lovell was knighted in 1961. He used the telescope to track and monitor flaring variable radio stars. Lovell has written many popular books on astronomy, radio astronomy in particular.

Low Surface Brightness Galaxies

Low surface brightness (LSB) galaxies are galaxies that emit much less light per area than normal galaxies. Because of their lower contrast with the night sky they are hard to find, and hence their contribution to the general galaxy population has long been underestimated.

Galaxies with low surface brightnesses are hard to find because the night sky is never black. Scattered sunlight coming from dust inside and outside our atmosphere, air-glow, street lights, faint Galactic and extra-Galactic sources all illuminate the sky. This foreground and background glare acts as a filter that only lets us see a part of the total galaxy population.

Compare this with the example of a person sitting inside a brightly lit room at night. This person will have trouble seeing what is happening outside because of the bright reflections of the room in the windows. Only the brightest objects (e.g. headlights of cars) will be easily visible. Headlights of bicycles, or pedestrians will be very hard to make out, even though they may dominate the traffic outside. The bright reflections thus filter out large parts of the total population.

In more practical terms, selection effects caused by the brightness of the night sky have made astronomers only give attention to those galaxies that were most easily observed. The underlying reason for these selection effects is that galaxy catalogs are usually created using certain isophotal diameter and/or magnitude limits (with an additional implicit surface brightness limit). The brightness of the night sky ensures that galaxies of a certain fixed luminosity look largest, and are thus most easily seen, if their central surface brightness has some intermediate 'optimum' value. If they have higher surface brightnesses they look too compact and resemble stars; with lower surface brightnesses they are difficult to distinguish from the night sky.

Diameter- or magnitude-limited catalogs thus mainly contain galaxies with a narrow range in central surface brightnesses. They will be biased and incomplete for galaxies with central surface brightnesses other than the 'optimum' value.

In the following, galaxies that are not affected by selection effects and that have an optimum value for detection are called 'high surface brightness' (HSB) galaxies. For all practical purposes these can be equated to the well-known SPIRAL GALAXIES that define the Hubble sequence. The dimmer galaxies that are affected by selection effects are called LSB galaxies. Examples are shown in figure 1.

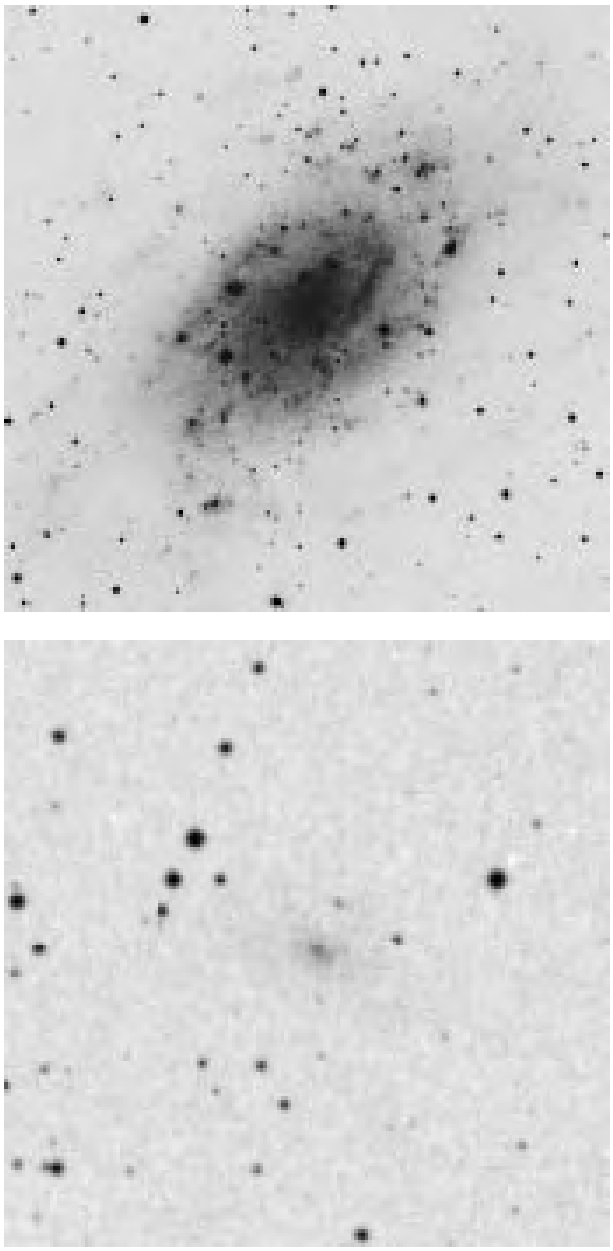

Figure 1. An HSB galaxy (NGC 2403, left panel) and an LSB galaxy (UGC 128, right panel) with identical luminosities, shown at the same physical scale, and observed with the same instrument. As the light of the LSB galaxy is much more spread out it is harder to distinguish from the glare of the night sky.

Selection effects

The best way to get a feeling for the severity of selection effects is by discussing a practical example. We will discuss five different types of model galaxies, which approximately span the currently known range in structural properties of DISK GALAXIES. All are assumed to be pure exponential disks, with central surface brightnesses μ_0 and scale lengths h as given in table 1. Four of these galaxies (A, B, C and D) have identical luminosities $M_B = -21$. The fifth one, E, is equal in size to galaxy B, but 2.5 mag or a factor of 10 fainter. It is furthermore assumed that all five types are spread through space homogeneously and in equal numbers. In each volume element there are therefore an equal number of different types of galaxies.

We will now 'observe' these galaxies and create a

Table 1. Contribution of various galaxy types in diameter-limited catalog.

Type[a]	M_B[b]	h[c]	μ_0[d]	$D_{\max}$[e]	Fraction	
A	−21.0	0.5	16.0	60	0.09	Compact HSB
B	−21.0	5.0	21.0	125	0.72	Normal HSB
C	−21.0	25.0	24.5	76	0.18	Big LSB
D	−21.0	50.0	26.0	—	0.00	Giant LSB
E	−18.5	5.0	23.5	30	0.01	Normal LSB

[a] Type of galaxy. [b] Absolute magnitude. [c] Scale length in kpc. [d] Central surface brightness in mag arcsec^{-2}. [e] Maximum distance in Mpc where galaxy is included in catalog. [f] Fraction of cataloged galaxies that will be of this type.

diameter-limited catalog. The condition for inclusion in the catalog will be that the diameter of the 25 mag arcsec^{-2} isophote D_{25} must be larger than 1 arcmin. It is obvious that galaxies at large distances will look smaller than those nearby. Therefore, as we examine each type of galaxy and move it to increasingly larger distances, its D_{25} will at some point become less than 1 arcmin, and consequently it will no longer be included in the catalog. The distance where galaxies of a certain type drop out of the catalog is given in table 1: galaxy A will drop out of the sample at 60 Mpc; galaxy B will be in the sample out to distances of 125 Mpc; galaxy C out to 76 Mpc. Galaxy D has no D_{25} diameter and will never be taken up in the catalog. Finally, galaxy E will be seen only out to 30 Mpc.

Galaxies of type B correspond to normal HSB galaxies, while type E represents typical LSB galaxies. Type C is a big LSB galaxy. Types A and D are in practice rare. Cataloged HSB galaxies (such as B) can be detected in a volume 72 times larger than the volume in which LSB galaxies (such as E) can be detected. Assuming that all types of galaxies are spread equally through space, the corresponding volumes cataloged galaxies occupy show that the catalog will be severely dominated by HSB galaxies of type B and will lead to the conclusion that almost three-quarters of the total galaxy population consists of type B. Only an apparently insignificant 1% of the galaxies in the catalog are of type E. Furthermore, we would not even know that giant galaxies, such as type D, existed. On the basis of these results we would conclude that three-quarters of the observed galaxy population had a constant central surface brightness.

To correct for these effects we must therefore realize that every LSB galaxy that *is* cataloged represents a large number of uncataloged LSB galaxies. This means that we must assign to every galaxy a weight inversely proportional to the volume in which it is included in the catalog. Hence, if we try to reconstruct the true galaxy population from this diameter-limited catalog, every LSB galaxy of type E must receive a weight 72 times larger than a galaxy of type B. Note though that we still would not be able to say anything about type D. These volume-correction factors are crucial for our understanding of LSB galaxies.

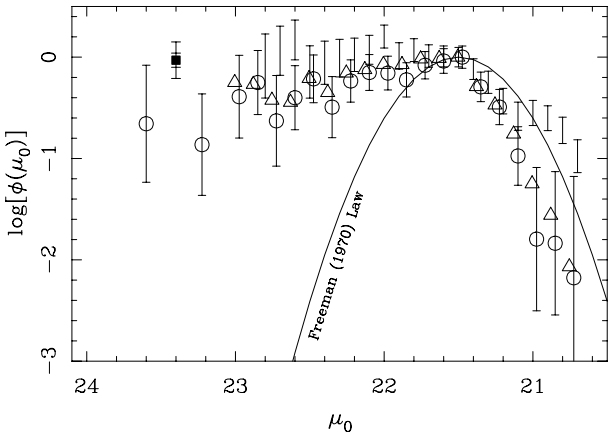

Figure 2. The number density of galaxies plotted versus central surface brightness. There is a large excess of galaxies at the LSB side of Freeman's value.

History

Selection effects and their possible consequences did not receive much attention until 3 decades ago. Before that only incidental references appeared in the literature. HUBBLE noted in 1936 that intrinsically faint galaxies will be detectable to much smaller distances than intrinsically bright galaxies and are consequently distributed through a much smaller volume of space. Thus 'intrinsically bright nebulæ greatly outnumber the faint ones among nebulæ with a given *apparent* luminosity'. In 1938 SHAPLEY announced the discovery of two intrinsically faint LSB galaxies, and in 1965 Arp showed that most galaxies then investigated occupied only a very narrow strip in a luminosity–diameter diagram; implying that they have almost identical surface brightnesses.

This last conclusion was explicitly derived by Freeman in 1970 who noted that 28 galaxies out of his sample of 36 had disks with central surface brightnesses in the range $\mu_0^B = 21.65 \pm 0.3$ mag arcsec^{-2}. Taken at face-value, this result had important implications for theories of GALAXY STRUCTURE and EVOLUTION. Freeman's law requires that either all galaxies have identical mass surface densities coupled with just a small spread in their mass-to-light ratios or that STAR FORMATION history, age, angular

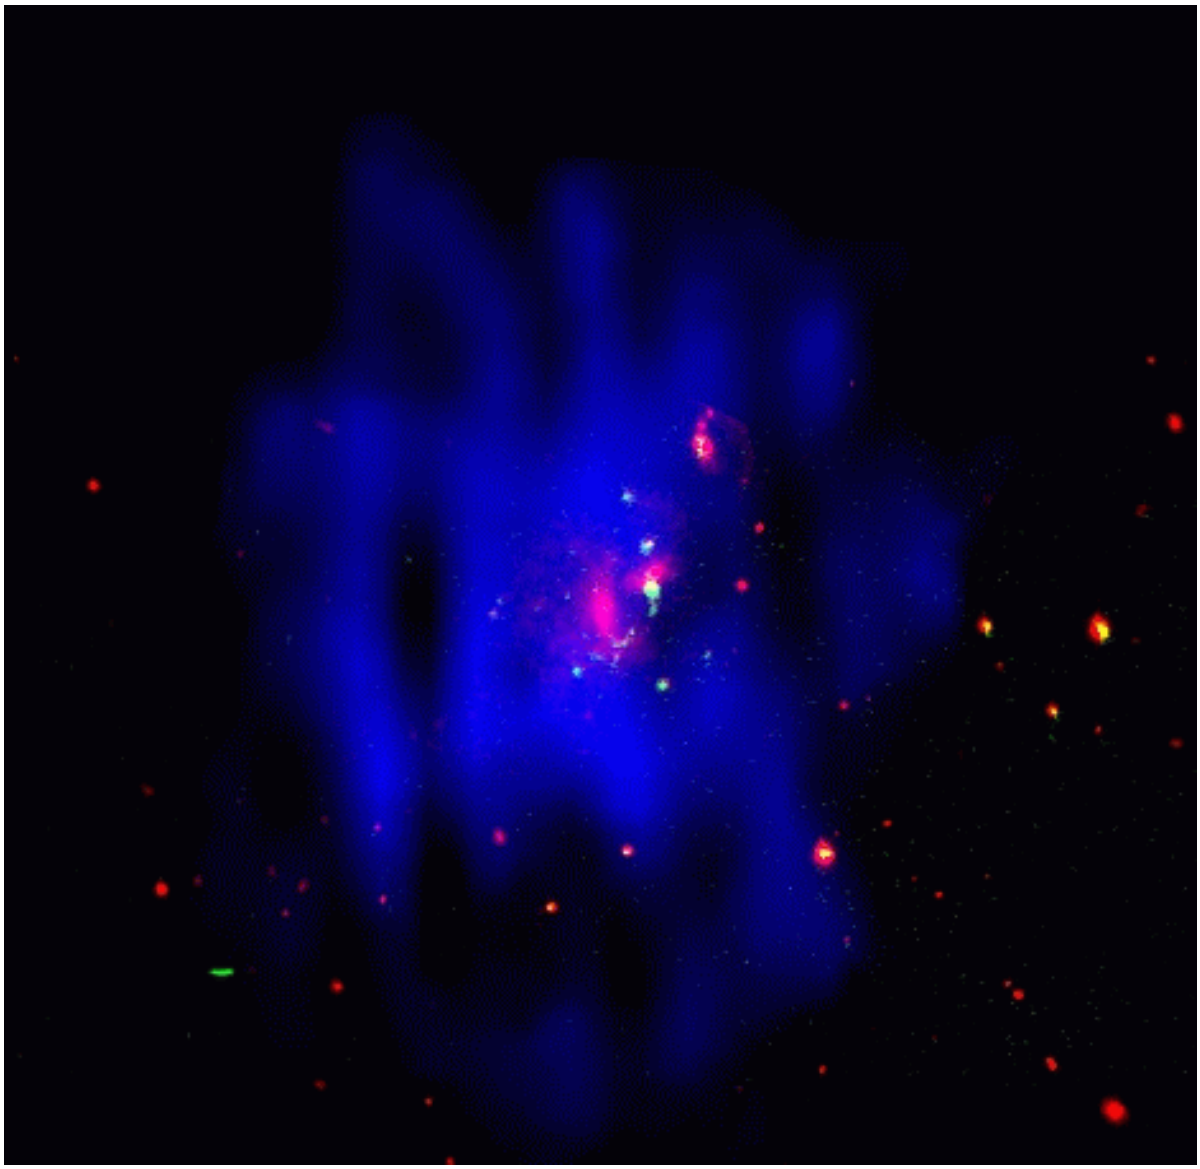

Figure 3. LSB galaxy F563-1. This false-color image is a combination of optical, 21 cm radio and 6563 Å Hα spectral-line observations. The red false colors show the stars in LSB galaxy F563-1 observed though a red filter. Blue false colors show the extent of the large and diffuse disk of neutral hydrogen surrounding the optical galaxy. The green–yellow dots in the center are observed in the light of the Hα spectral line at 6563 Å, showing the few star formation regions in this galaxy. The red and yellow dots surrounding the galaxy are foreground stars. The gas and stars in this galaxy represent a mass of a few billion solar masses, yet this is only a small fraction of the mass of the huge dark matter halo that surrounds this galaxy. This galaxy is at a distance of 45 Mpc or 147 million light-years. The diameter of the neutral hydrogen disk is 43 kpc or some 140 thousand light-years. **This figure is reproduced as Color Plate 12.**

momentum and mass all conspire to produce a constant central surface brightness

Disney in 1976 showed that selection effects could cause Freeman's law and suggested that there might be many galaxies of both high and low surface brightness ('crouching giants') hidden below the night sky. The discovery in 1987 of the giant LSB galaxy Malin-1 put LSB galaxies in the limelight. This extremely large and massive LSB galaxy was discovered accidentally during a survey for small LSB galaxies in the VIRGO CLUSTER. Malin-1 has a central disk surface brightness 4 mag arcsec^{-2} fainter than Freeman's value, yet it has a scale length of tens of kpc, a luminosity $M_B \simeq -22$ and an H I mass of slightly less than $10^{11} M_\odot$. This did show that LSB galaxies were not necessarily small and faint dwarf galaxies.

Careful searches on photographic survey plates then started turning up LSB galaxies in large numbers. These galaxies were mostly of late type and rich in hydrogen.

After correction for various selection effects one of the conclusions was that the space density of LSB galaxies at $\mu_0 = 23$ is approximately 10^5 times higher than predicted by Freeman's law (figure 2).

The currently known LSB galaxies ($25 < \mu_0(B) < 23$) may make up 30–50% of the total galaxy population.

Properties

The properties of LSB galaxies can be summarized as follows.

They are more gas rich than HSB galaxies. One of the probable reasons they have lower surface brightnesses is because their gas surface densities are well below the critical threshold density for star formation. LSB galaxies thus have very low star formation rates. Although following the large-scale structure of galaxies, they are locally more isolated than other galaxies.

Investigations of the colors of LSB galaxies showed that they were bluer than normal late-type galaxies. Combined with the low metallicities found in H II REGIONS this implies a sporadic star formation rate, ruling out the notion of LSB galaxies as 'faded disks'. LSB galaxies are not normal galaxies which have stopped forming stars and are now fading away. Instead, they are likely to be slowly evolving. The contrast of the few young stars with the old background population, or, in other words, the rate of current star formation rate and average past star formation rate are much higher than in normal HSB late-type galaxies. A small amount of recent star formation (as observed) is already enough to make the colors significantly bluer.

Synthesis observation in the neutral hydrogen 21 cm line (see figure 3) confirmed this unevolved picture: LSB galaxies have extended gas disks with low gas surface densities, and high $M_{\rm HI}/L$ ratios. Despite the low surface densities the gas component is usually dynamically more important than the stellar component.

LSB galaxies are on the same TULLY–FISHER RELATION as HSB galaxies. This requires a subtle interplay between the central luminosity surface density Σ_0 and the total mass-to-light ratio M/L. As the Tully–Fisher relation can be written as $L[\Sigma_0(M/L)] \propto V^4$, the product $\Sigma_0(M/L)$ must be constant for all galaxies on the Tully–Fisher relation. LSB galaxies must have higher mass-to-light ratios than normal galaxies.

The rotation curves of LSB galaxies showed that this was indeed the case. LSB galaxies are DARK MATTER dominated almost all the way into their centers. The rotation curves rise less steeply than those of HSB galaxies. The halos of LSB galaxies are likely to be of lower density than those of HSB galaxies. The large dark matter dominance makes the stellar disks of LSB galaxies extremely stable, making it possible for the disk to exist at such low surface densities. The low metallicities make cooling difficult, so that a molecular component, where stars are formed, is difficult to realize. LSB galaxies can be said to be trapped in their current evolutionary state. Even external influences, like interactions, might not be enough to significantly speed up the evolution of LSB galaxies.

The above results apply to blue LSB galaxies that have been discovered in photographic plates. Recent CCD surveys (see also DETECTION OF FAINT OBJECTS) have started turning up a class of red LSB galaxies, showing that even the deep photographic plates suffered from selection effects. However, not enough is known about these red LSB galaxies to be able to say whether they are a cosmologically significant component of faded galaxies.

Importance

The single most important reason for studying LSB galaxies is that no representative sample of nearby galaxies has yet been compiled, cataloged and investigated. If a large population of hitherto unseen objects exists, the true extent of galaxy properties may be much larger than assumed.

Furthermore, investigations of individual LSB galaxies show that they form an alternative track of galaxy evolution, free from the instabilities and interactions that have shaped the Hubble sequence. They give us the opportunity to study unevolved galaxies in great detail.

Lowell Observatory

Lowell Observatory, founded in 1894 by Percival Lowell, is one of the largest independent, privately managed observatories in the world. Endowed by its founder, Lowell Observatory continues today as a private research institution dedicated to the study of astronomy. The large redshifts of galaxies were discovered by Lowell astronomer Vesto M Slipher. In 1930, Clyde Tombaugh discovered Pluto at Lowell Observatory.

Today, Lowell Observatory has a staff of 50, including 20 astronomers. The Observatory operates eight telescopes: four at its original campus on Mars Hill and four at a dark-sky site on Anderson Mesa, southeast of Flagstaff, Arizona. Lowell is a partner with the US NAVAL OBSERVATORY and the Naval Research Laboratory in the Navy Prototype Optical Interferometer (NPOI) at Anderson Mesa and with Boston University in the shared use and development of Lowell's 72 in (1.8 m) Perkins Telescope.

The Observatory is engaged in research spanning many areas in modern astronomy and astrophysics, while maintaining its traditional emphasis on study of the solar system. In addition to funds from the original endowment, a significant component of the Observatory's support is from federal grants and contracts.

For further information see http://www.lowell.edu/.

Lowell, Percival (1855–1916)

Businessman, traveler, diplomat and, eventually, astronomer, born in Boston, MA, into a distinguished family (younger brother a president of Harvard University, sister a writer). His boyhood interest in astronomy revived at the age of 37, when after correspondence with WILLIAM H PICKERING they set up an expedition to observe the 1894 Mars opposition from the clear skies of Arizona. They founded the *Lowell Observatory* at Flagstaff, seen as a 'speculative, highly sensational and idiosyncratic project' to study the solar system as 'an investigation into the condition of life on other worlds, including . . . their habitability by beings like or unlike man'. Lowell had, unobjectively, already made up his mind about the implications of SCHIAPARELLI's identification of a network of canali on Mars: 'The most self-evident explanation from the markings themselves is probably the true one; namely, that in them we are looking upon the result of the work of some sort of intelligent beings'. Lowell studied Mars for 15 years, noting the spring-time dark band around the south pole, described as a 'ring of antarctic ocean', which fed the green 'vegetation' of the dark areas. He drew Mars in exquisite and imaginary detail, covering its map with a network of hundreds of straight 'canals' intersecting in 'oases'. According to JAMES KEELER, writing to GEORGE HALE (co-editors of the *Astrophysical Journal*) Lowell's papers were written in a 'dogmatic and amateurish style', and 'he draws no line between what he sees and what he infers', an opinion which led to the *Astrophysical Journal* refusing to publish any of Lowell's submissions. Lowell used the last eight years of his life to search for a trans-Neptunian planet, having analysed the orbit of Uranus and found discrepancies even after allowance for Neptune. He was unable to find the planet, but his search was continued after his death by CLYDE TOMBAUGH at Flagstaff, with Pluto discovered in 1930. The first two letters of Pluto, and the symbol for the planet, are Percival Lowell's initials.

Luminosity Function of Galaxies

The definition of the (optical) luminosity function (LF) of galaxies follows those of other astronomical objects such as stars or globular clusters. It is the number of galaxies that exist in a given volume of space having a given luminosity. Thereby, 'luminosity' generally means a total magnitude in any photometric passband U, B, V, R, I, etc. However, because of the spectral sensitivity of photographic plates which were classically and still are used for LF studies most of our knowledge is based on B- and R-band photometry. More recent work utilizes modern wide-field CCD cameras and infrared detectors to explore the LF of galaxies at other wavelengths.

Galaxies span a large range in total visual luminosity. At the extreme ends we find huge stellar systems with $L_B \sim 5 \times 10^{10} L_\odot$ ($M_B \sim -22$) such as the giant elliptical galaxy Messier 87 in the nearby VIRGO CLUSTER and the 5×10^5 times fainter dwarf elliptical galaxies Draco and Ursa Minor in the LOCAL GROUP with integrated blue light emission $M_B \sim -7.5$ comparable with a single massive main-sequence star.

The LF of galaxies is an important observational ingredient for cosmology as well as for galaxy formation and evolution. It holds fundamental information about (i) the power spectrum of the primordial density fluctuations, (ii) the physical processes that convert mass into light, e.g. gravitational collapse, cooling and star formation, and (iii) the mechanisms that destroy–generate galaxies or change their morphology such as tidal interaction, merging and ram pressure stripping. As such the LF is essential to interpret the huge apparent population of faint blue galaxies discovered at intermediate redshift ($z \approx 0.5$), to estimate the luminosity and baryonic densities of the universe and to test models of galaxy formation and evolution, e.g. the popular concept of 'biased galaxy formation'. Often the quality of a theory is assessed on how well the shape of the observed LF can be explained.

In the following we give a short historical overview about the discovery of the LF of galaxies and provide details of various observing techniques. We further explain the main features of a typical LF and discuss why nature makes LFs drawn from different parts of the universe not always look the same. We conclude with some remarks on crucial issues that are important for a deeper understanding of the LF of galaxies in the future.

A historical retrospect

The first result on the LF was published by Edwin Hubble in the mid-1930s initiated by the evidence that the velocity–apparent magnitude relation for the Shapley–Ames galaxies studied by Milton Humason exhibit only a small scatter. Interpreted in the context of a linear expansion of the universe, i.e. velocity proportional to distances (HUBBLE LAW), these observations meant that the width of the absolute magnitude distribution, i.e the LF, of these galaxies was also small. Hubble's results, although they lacked precision, suggested a Gaussian profile centered at $M_B \sim -18$ and $\sigma \sim 0.9$ mag. There seemed to be upper and lower limits for galaxy luminosities. In 1942, the validity of a bell-shaped form for the LF was called in question by Fritz Zwicky who predicted from thermodynamical considerations (principle of conservation of energy, virial theorem and Boltzmann principle) the existence of a large number of low-mass, faint dwarf galaxies in the universe and consequently a steeply rising LF towards fainter luminosities. Even though most of these dwarfs remained undetected at that time, Zwicky's idea received some support from discoveries of very faint dwarf galaxies in the Local Group.

These apparently controversial historical results exemplify the problems LF research encounters: selection bias and incompleteness. Hubble's primary goal was to measure redshifts and hence he had to concentrate on high surface brightness galaxies: ELLIPTICALS (E), LENTICULARS (S0) and SPIRALS (Sp). In this way the numerically dominant galaxy types in the universe, which we know today are the hardly visible low surface brightness DWARF IRREGULAR (dIrr) and DWARF ELLIPTICAL GALAXIES (dE), did not contribute to his consideration. Zwicky's theoretical result, on the other hand, found assistance from a spatially well-defined galaxy aggregate where the number of known dwarf galaxies was small but steadily increasing with time. Hence the Local Group catalogue reflected the actual situation much better.

Cluster versus field

When searching for galaxies across a photographic plate the eye is quickly caught by galaxy clusters which exhibit a high density contrast against the general field. Because of their nature clusters are the best places to perform LF studies. They inherit many hundreds of galaxies of all different morphological types which are all located in a small volume of space. Hence the cluster distance D, averaged over a fair number of individual known galaxy distances, can be used to convert apparent magnitudes m of all cluster members into luminosities ($M = m - 5 \log[D\,(\mathrm{Mpc})] - 25$). The identification of cluster members against background and foreground objects requires the cluster to be well isolated in real and velocity space to keep contamination by non-cluster galaxies minimal. The bright E, S0 and Sp galaxies are identified based on velocity data and/or morphological criteria. At fainter luminosities most galaxies are dwarfs for which velocities are not easily accessible. The numbers of these galaxies are estimated statistically by comparing galaxy counts in a cluster with an adjacent reference field. The excess in the measured cluster LF is assigned to the cluster population. However, the heterogeneous distribution of field galaxies makes this procedure difficult and a matter of dispute. Alternatively, the unique morphological appearance of dwarf galaxies, in particular dE galaxies, provides an excellent tool to decide which object belongs to a cluster. The drawback with this method

is the requirement for galaxy images of high angular resolution, which technically restricts the application to the closest clusters.

The field LF is much more difficult to measure. About 80% of all galaxies reside outside of rich clusters where galaxy densities are down by a factor of 100–1000. Large volumes must be surveyed to obtain representative samples of objects. Panoramic and pencil-beam surveys are carried out for this purpose using long integration times to reach low surface brightness galaxies and bright stellar systems at larger distances. Redshifts (velocities) are the backbone for field LF studies as they provide the important distance information. Employing the velocity as a distance indicator becomes possible because gravitationally induced peculiar velocities are mostly absent in the field and thus observed velocities are closely linked to the Hubble flow (the general expansion of the universe), although corrections for large-scale bulk motions are still required. Field surveys have generally an apparent magnitude limit owing to the sensitivity limits of the spectrographs. This means that intrinsically bright galaxies always predominate in galaxy samples as they are visible over large distances. To fainter luminosities the surveyed volumes shrink substantially and the galaxy numbers drop significantly. For instance the detection volume for the Small Magellanic Cloud is 4000 times smaller than for M87 just because of the difference in their total magnitudes. At that level inhomogeneities in the three-dimensional galaxy distribution do not always average out and can cause biases in the data (see DISTRIBUTION OF GALAXIES, CLUSTERS AND SUPERCLUSTERS). Various sophisticated methods exist to estimate the LF from a magnitude-limited galaxy sample (the $1/V_{\max}$, C and STY methods to name the most important ones), however the substantial corrections at the faint end of the LF make the shape in any case highly uncertain.

Overall and type-specific LFs

Since 1970 more than 100 cluster and field studies contributed to reveal the overall signature of the LF (see figure 1): after an exponential rise at $M_B \sim -22$ ($H_0 = 50$ km s^{-1} hereafter) the LF turns off at a characteristic luminosity L^* (total magnitude M^*), which is sometimes referred to as the 'knee', and follows a power law at fainter luminosities. The most popular parameterization to fit the data was proposed by Schechter in 1976:

$$\phi(L)\,\mathrm{d}L = \phi^*(L/L^*)^{\alpha}\,\exp(-L/L^*)\,\mathrm{d}(L/L^*) \qquad (1)$$

with the normalization parameter ϕ^*, or equivalently in magnitudes

$$\phi(M)\,\mathrm{d}M = (0.4\ln 10)\phi^* 10^{0.4(M^*-M)(1+\alpha)} \times \exp[-10^{0.4(M^*-M)}]\,\mathrm{d}M.$$

Thereby the faint-end slope is given by $-(1+\alpha)$, i.e. decreasing for $\alpha > -1$, flat for $\alpha = -1$ and increasing for $\alpha < -1$. The integral of equation (1) yields the total number of galaxies in a given volume in space whose luminosities are brighter than L: $N(>L) = \int_L^\infty \phi(L')\,\mathrm{d}L' = \phi^*\gamma(1+\alpha, L/L^*)$. Their total luminosity is $L_{tot}(>L) = \int_L^\infty L'\phi(L')\,\mathrm{d}L' = \phi^* L^*\gamma(2+\alpha, L/L^*)$, where γ is the incomplete gamma function.

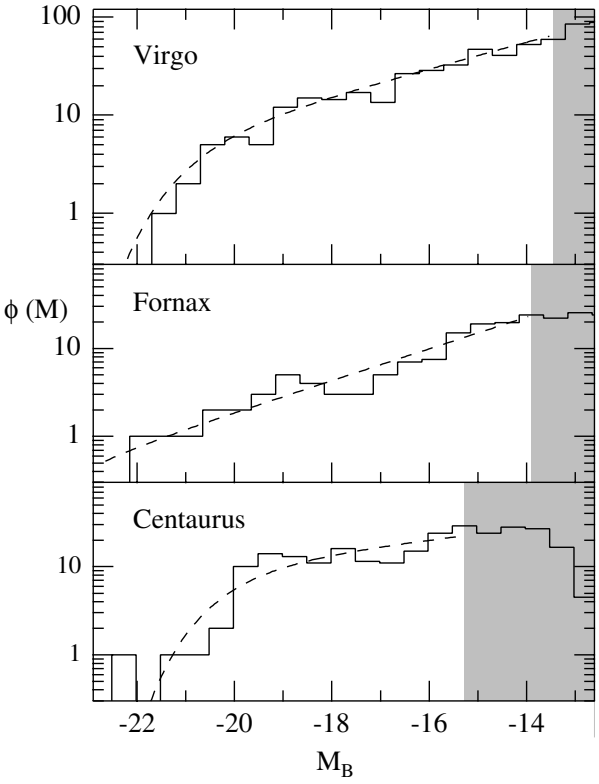

Figure 1. Data from the three clusters Virgo, Fornax and Centaurus (histograms) illustrate the diversity in observed cluster LFs. By chance Virgo is exceptionally well fitted by the Schechter form (dashed curve), whereas the local features in the LFs of Fornax and Centaurus remain unresolved. The shaded areas indicate the sample incompleteness intervals.

The Schechter function describes reasonably well the observed cluster LFs (see figure 1). Mismatches occur at the bright end owing to the presence of overluminous cluster members or if the LF is rich in local features. Nevertheless, the apparent good agreement led to the suggestion that the values $M_B^* \sim -21.0$ (about the total magnitude of the Andromeda galaxy) and $\alpha \sim -1.25$ might be of physical significance. However, this idea was not further supported by subsequent deeper surveys of clusters of various densities, richnesses, morphological classes or evolutionary stages which found a wide range of faint-end slopes ($-2.2 < \alpha < -0.9$). It was also noticed that the Schechter parameters are strongly correlated and vary significantly with the depth of a survey. The latter means that the same cluster population analyzed to different magnitude limits will not necessarily give the same Schechter parameters. Robust solutions cannot be expected above $M_B \sim -14$.

In contrast to clusters where the signature of the environment is still imprinted on the data, the LF for field populations (including groups) gave quite a consistent picture with $M_B^* \sim -21.0$ and a flat LF down to $M_B \sim -17$. However, it is not very surprising after the previous remark that this result has been revised in recent years by deeper redshift surveys ($M_{B,lim} \sim -15$) reporting on prominent deviations from a flat LF ($-1.3 < \alpha < -0.7$). The disturbing point now is the observed scatter in α. Wouldn't we expect a well defined, unique asymptotic behavior of the field LF if averaged over a cosmological meaningful volume? This discrepancy has to be resolved in order to understand possible selection biases in the data, limitations of incompleteness corrections and eventually real differences in the dwarf-to-giant ratio for a given survey area.

After learning about all the differences between the LFs of high- and low-density regions and even among various clusters hope is dwindling that the observed spectrum of LFs can be reduced to a common denominator. However, on looking more carefully one immediate explanation comes into mind: the galaxy type mixture which intimately correlates with the environmental density. This phenomenon encompasses (1) the well-known GALAXY MORPHOLOGY–DENSITY RELATION: early-type galaxies (E, S0, dE) preponderate in the high-density regions whereas late-type galaxies (Sp, dIrr) dominate the intercluster medium, i.e. groups and field, and (2) the observation that the dwarf-to-giant ratio is correlated with the local density. These trends automatically open the question on the LFs of individual morphological galaxy types.

Our knowledge on the type-specific LFs is still in its infancy. Work started in the 1980s with first results on the Coma cluster, followed by extensive studies of the three nearby clusters Virgo, Fornax and Centaurus. Based on detailed morphological information the above-mentioned five main galaxy families could be studied individually. The results suggest that the type-specific LFs are very different but that each, except the dIrr LF, show little or no variation from one cluster to the other. The classical Hubble types E, S0 and Sp exhibit bell-shaped LFs; they exist only above a certain threshold luminosity. Dwarf galaxies are less luminous than the giants and govern completely the overall LF for galaxies fainter than $M_B \sim -16$. The large populations of dE galaxies in clusters show a steep Schechter-like LF with a mean α of -1.4. The most puzzling LF is that of the dIrrs with α values between -1.3 and -0.3. The large scatter may have its origin in the definition of the dIrr class that encompasses hardly visible low surface brightness galaxies (Im) with no or very little recent star formation activity and bright compact starburst galaxies (BCD). Difficulties in detecting the faintest members of the family can introduce selection biases to the data. However, density-dependent mechanisms that trigger star formation would also affect the LF of these gas-rich dwarfs.

The morphological resolution of field galaxies is not as accurate as for nearby cluster galaxies owing to the larger distances involved. Spectra are used instead to subdivide galaxies according to their level of star formation, a quantity that is closely related to the basic branches of early-type (E, S0, dE) and late-type (Sp, dIrr) galaxies at the present epoch. Recent deep-redshift surveys of many thousand galaxies in the redshift range $0 < z < 1$ sampled the type-specific LFs in the field as faint as $M_B = -15$. The results are qualitatively consistent with Gaussian profiles for the E–S0, and Sp galaxies and with steep LFs for dEs and dIrrs. It is interesting to note that an apparent steep dIrr LF at that magnitude limit is not necessarily in contradiction with an asymptotic value $\alpha = -1$ as illustrated in figure 2 (see 'Extreme Field'). The large number of dIrrs scales a flat dIrr LF upwards leading to a steep slope at $M_B = -15$.

The evidence for invariant type-specific LFs offers for the first time a semi-empirical tool to explore the behavior of the overall LF as a function of the environment. For this purpose the five type-specific LFs as found in three clusters (table 1) are weighted with observed and, in the case of the 'Extreme Field', hypothetic type mixtures to generate synthetic overall LFs. Similarly to working with the same ingredients but using different recipes so that the result is either a cake or a custard, this approach produces the whole range of observed LFs (see figure 2) from rich, dense clusters like Coma and loosely concentrated systems like Virgo to groups and the field. The very different characteristics of LFs from clusters to the field are explained satisfactorily with this method, which clearly indicates the importance of the type mixture and type-specific LFs for the understanding of the overall LF.

Table 1. Analytical functions and parameters that represent good first-order approximations for observed type-specific LFs in galaxy clusters. The faint-end slope for dIrrs is assumed to be -1 owing to the lack of conclusive empirical results.

E	Gauss	$\mu_B = -18.3$	$\begin{cases}\sigma_{M<\mu_B} = 2.2\\ \sigma_{M>\mu_B} = 1.3\end{cases}$
S0	Gauss	$\mu_B = -18.9$	$\sigma = 1.1$
Sp	Gauss	$\mu_B = -18.3$	$\sigma = 1.4$
dIrr	Schechter	$M_B^* = -16.2$	$\alpha = -1$
dE	Schechter	$M_B^* = -17.8$	$\alpha = -1.4$

Summary and prospects

Generally speaking there is a good understanding of the optical LF of galaxies down to a luminosity $M_B \sim -16$ but unfortunately this is still far away from the complete picture. The most basic detail is that the LF is the sum over separate LFs for the individual galaxy types. There are two major components in the overall LF which have been effectively discovered by Hubble and Zwicky. The first component consists of the three families of high surface brightness galaxies E, S0 and Sp. The second component is made up by the dwarfs, low surface brightness galaxies which are intrinsically

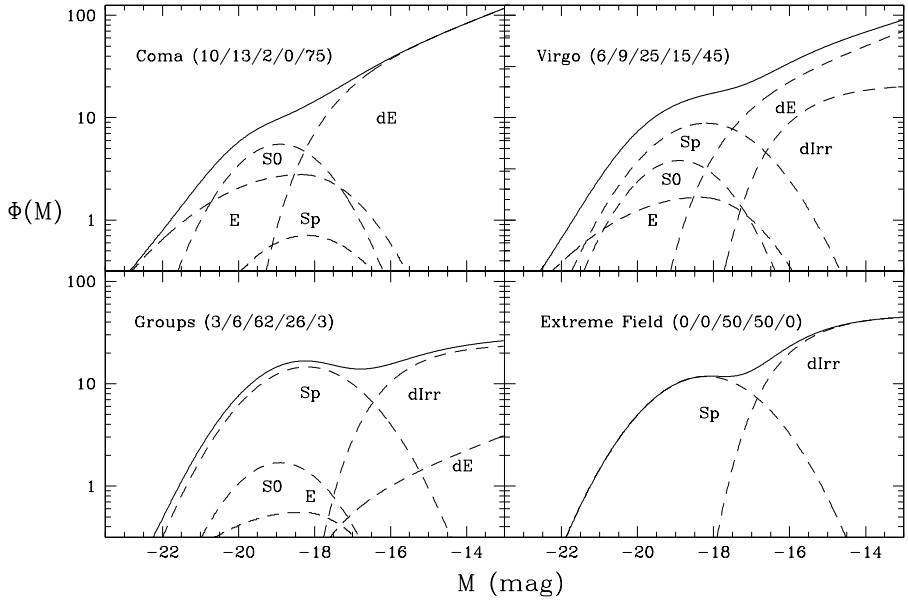

Figure 2. Synthetic overall LFs (solid curves) for four different environments with the galaxy type mixtures (E:S0:Sp:dIrr:dE) indicated as percentages. The contributions of the five main morphological types are the dashed curves.

fainter than the giants and fully control the asymptotic behaviour of the LF in all environments. This can be either a steep or moderate–flat power law depending on the local galaxy density. Due to the very different nature of the two components, many clusters (e.g. Fornax, Centaurus, Coma, Abell 963), some groups (e.g. Antlia) and field populations exhibit a prominent dip in their LFs at the transition luminosity $M_B \sim -17.5$.

Fundamentally we would like to fully understand the formation and evolution of galaxies. Results on the LF clearly indicate that this goal cannot be achieved by treating the phenomenon 'galaxy' as unity. Rather, the various morphological types have to be studied individually. From cluster work first evidence emerges that the LFs for E, S0 and Sp at the present epoch have well-defined Gaussian profiles which are unaffected by the environment. The same appears to be true for the LF of dE galaxies which follows a steep Schechter profile to all known luminosity limits. For the dIrr LF we are still lacking conclusive results as the situation is far more complex. There are some physical arguments against a single LF for dIrrs in clusters. Overall, more detailed LF studies in the local universe and at different redshifts, i.e. time epochs, are desperately needed, focusing on the separation of the morphological components in a consistent way. These results will reveal the significance of time and environmentally induced physical processes for the evolution of galaxies.

Another key issue is the variation of the morphological mixture with galaxy density and the dwarf-to-giant ratio in particular. Most current cosmological theories predict that, as the universe expands, galaxies clump together to form groups, which in turn merge together to form clusters. These 'bottom-up' scenarios have difficulties in explaining the high dwarf-to-giant ratio in clusters compared with the lower fraction in groups and the field. Where is this 'excess' of cluster dwarfs coming from? That question is fundamentally related to the space density of dIrrs which is not very well known as the faintest members of these dwarfs may remain undetected in the optical. However, this situation is going to change with systematic surveys of the local universe in neutral hydrogen (H I). dIrrs contain a substantial amount of H I gas and thus become 'visible' by their radio emission at 21 cm. Another advantage of H I surveys over optical work is that each galaxy is automatically tagged with its distance via the H I velocity. Preliminary results for nearby groups from ongoing H I surveys (e.g. HIPASS) are very promising. Many new group members have been discovered in H I but all have faint optical counterparts. Firstly this means that the average number of dIrrs and the dwarf-to-giant ratio in groups are higher than estimated to date. Secondly, the H I mass-to-light ratio for dIrrs is not increasing with fainter luminosities. The missed fraction of dIrrs per magnitude unit appears to be small which gives us greater confidence in the optical results.

Luminous Blue Variables

Luminous Blue Variable stars (LBVs) are among the most luminous hot stars in galaxies. They show very irregular and unpredictable brightness variations. The typical timescale of the variations is of the order of a few years and the visual brightness of the star can vary by about a magnitude. Some LBVs have suffered very large eruptions. LBVs represent a short critical phase in the evolution of very massive stars (see also STELLAR EVOLUTION).

LBVs are highly unstable, very luminous stars. They are recognized by their strange variability on many timescales. The most characteristic variations show brightenings or fadings by a factor of two or three over a period of years. Some LBVs are changing all the time; others go through phases of about constant brightness that may last ten years before they start changing again. Observations with satellites have shown that when these stars are faint in visual light, they are bright in UV radiation and vice versa. This shows that the variations are due to changes in the radius and surface temperature of the stars. During the visually faint phases, the stars are relatively hot and small. When they are visually bright their surface temperature drops but their radius increases by a factor between two and ten. The reason for these changes is still unknown.

Several LBVs have been observed to go through large eruptions, when they brighten by as much as a factor of 100. Such eruptions are rare and may occur only once every few thousand years. During an eruption the LBV ejects a large amount of mass, of the order of the total mass of the Sun. The most famous LBV is the star η Carinae (ETA CARINAE), which had an eruption in late 1830s, when it suddenly became one of the brightest stars in the Southern sky. The star is now surrounded by a magnificant bipolar NEBULA consisting of the gas ejected during the eruption.

LBVs are very rare: there are only five confirmed LBVs in our Galaxy and a few tens in other galaxies. This is because they represent a relatively short phase in the life of the most massive stars. Yet, this phase is critical for the evolution of these stars: the large mass loss of the LBVs prevents the massive stars from becoming red supergiants. After the LBV phase they have lost so much mass that they evolve directly into very hot helium-rich stars (the WOLF–RAYET STARS).

Two special LBVs

P Cygni

The star P Cygni was discovered in the constellation of Cygnus the swan in August 1600 by the Dutch cartographer Bleau, when it suddenly appeared at a place where no star had been visible before. The star remained bright for many years and then slowly faded untill it was invisible to the naked eye. In 1655 it brightened again for a few years but was invisible during the late 1600s. Now the star can be seen with the naked eye (at magnitude 4.9). From the distance of the star, 6000 light-years away, and from the brightness in visual and ultraviolet light, it is concluded that the star has a radius of 76 solar radii, a surface temperature of 19 000 K and a mass of about 30 times that of the Sun.

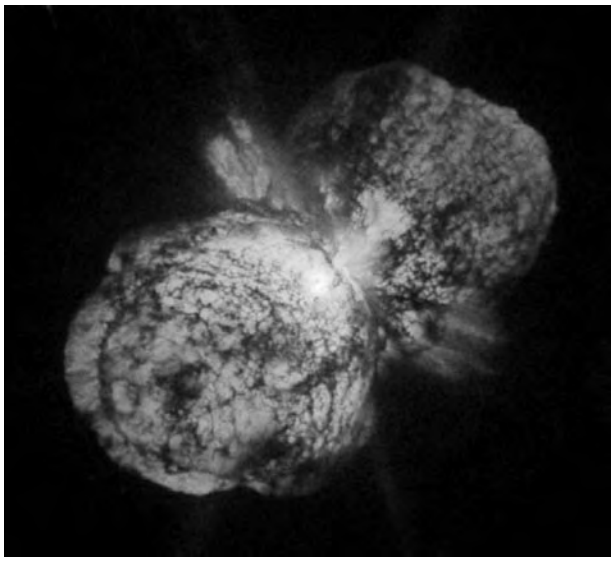

Figure 1. The nebula around the Luminous Blue Variable η Carinae is the result of the large eruption in the mid 1800s. This image was taken with the Hubble Space Telescope.

The historic light curve shows that since 1700 the star has been slowly brightening at a rate of 15% per century. This is interpreted as a very slow expansion of the star due to its evolution from blue to yellow supergiant. P Cygni is surrounded by a very faint nebula, which is the result of the ejection during the large eruption in 1600. The nebula was ejected wih a velocity of 140 km s^{-1}.

η Carinae

The most dramatic brightness variations of any LBV is shown by η Car. During the eruption in the period of 1837 to 1860 the star was the brightest star in the Southern sky, despite its large distance of about 8000 light-years. At maximum, the star reached a luminosity of 30 million times that of the Sun. It faded rapidly after the eruption, because it was obscured by the dust that had been formed in the ejected material. Since the mid-1900s the star has gradually brightened in visual light as the extinction by dust decreases.

η Car is surrounded by a spectacular nebula consisting of gas and dust ejected during the large eruption (figure 1). The nebula has a double-lobed structure, with an expansion velocity of about 30 km s^{-1} near the center to 1000 km $^{-1}$ at the outer edge. The total amount of mass in the nebula is about ten times the mass of the Sun. The typical bipolar structure is not explained: it could be due to the fact that η Car may have a companion star nearby, or due to rapid rotation of the star. Unfortunately the star itself is hidden in the central region of this nebula. The star can only be studied through its light reflected from the dust cloud surrounding it. This has shown that the

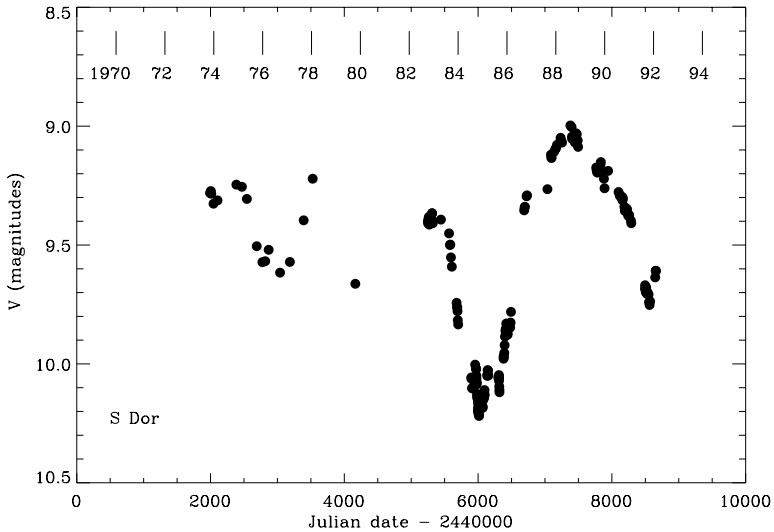

Figure 2. The light curve of the LBV S Doradus in visual light between 1975 and 1992. Bright is up, faint is down. An increase of one magnitude corresponds to a decrease in brightness by a factor 2.51.

central object varies in emission lines, especially those of hydrogen and neutral helium, with a period of 5.52 years. This suggests that the central object is in fact a BINARY SYSTEM consisting of two stars of about 80 solar masses orbiting each other at a distance of about 20 astronomical units. The binarity may have been responsible for shaping the bipolar nebula.

The light variations of LBVs

The light curves of LBVs are highly irregular and unpredictable. A typical light curve of the LBV star S Doradus is shown in figure 2.

Three types of light variations can de distinguished in the light curves of LBVs:

(a) Short time variations on a timescale of months with an amplitude of 0.1 to 0.3 magnitudes (the little wiggles near the deep point of the curve of figure 2).
(b) Typical LBV variations on a timescale of years with an amplitude of about 0.5 to 1 magnitude (the large dips and peaks in figure 2).
(c) Large eruptions that have been observed in P Cygni and η Carinae, but not in S Doradus. The presence of nebulae around LBVs indicates that most, if not all, LBVs go through large eruptions, and that these may occur every few thousand years.

The short time variations are caused by NON-RADIAL STELLAR PULSATIONS. Normal hot supergiants show the same type of pulsations (sometimes called α Cygni variations). The much larger typical LBV variations (sometimes called S Doradus variations) are due to some unknown instability inside the star that makes the radius grow and shrink in an irregular way by up to a factor of ten. During these variations the total luminosity of the star remains almost constant but the light is redistributed in the visual and the ultraviolet. This means that as the radius expands, the surface of the star gets cooler, and so the color of the star gets redder and the spectral type changes from early-B to A-type. These changes are indeed observed during the light variations. The origin of the large eruptions is unknown. It may be related to the fact that the stars are so luminous that the outward directed force due to radiation pressure is almost as large as the inward directed gravitational force. In that case the net attracting force inside the star can be so small that even minor disturbances can create a large instability.

Basic properties

The basic properties of well studied LBVs are listed in table 1. This list contains the five confirmed Galactic LBVs and five LBVs in the LARGE MAGELLANIC CLOUD.

Luminosities

LBVs are very luminous with a luminosity, L, between 260 000 and 3 400 000 times that of the Sun. The luminosity of the LBVs remains almost constant during their variations in visual brightness and in color.

Surface temperatures

The effective temperatures, $T_{\rm eff}$, of LBVs vary with the visual brightness. At visual maximum the stars have a temperature of about 8000–9000 K. At visual minimum the LBVs are much hotter, from 30 000 K for the most luminous ones to 10 000 K for the least luminous LBVs. The changes in temperature are correlated with the visual brightness variations. The larger the visual brightness variations, the larger the temperature differences. This is because the decrease in visual light is compensated by an increase in the ultraviolet light as the star becomes hotter. The stars η Carinae and P Cygni, which do not show typical

HD 160529	Galaxy		290 000	8 000–11 000	280–150	no
R 110	LMC	51000	290 000	7 600–10 000	300–180	no
R 71	LMC	51000	260 000	9 000–14 000	200–90	yes

LBV variations with amplitudes of about a magnitude, also show little temperature variation, except during their historic large eruptions.

Radii

The radius of LBVs varies with the effective temperature. High temperatures correspond to small radii and vice versa. During the hot and visually faint phase the radius is typically between 40 and 100 solar radii (except for HD 160529 and R 110). During the cool and visually bright phase the radius is typically a few hundred solar radii. This is in agreement with the almost constant luminosity of the LBVs during their variations, which implies that the radius is approximately proportional to $T_{\rm eff}^{-2}$.

Masses

The masses of LBVs are not well known. The high luminosity of the stars indicates that their original mass is in the range from 40 solar masses for the least luminous LBVs, like HD 160529, R 110 and R 71, to 100 solar masses for the most luminous ones like AG Carinae and R 127. The star η Carinae is by far the most luminous and most massive one with an estimated initial mass of 150 solar masses. The actual (present day) mass of the LBVs is considerably smaller than their initial mass. The nebulae around many the LBVs show that they have lost a significant fraction of their initial mass already. Evolutionary calculations suggest that the masses of LBVs are between 40% and 75% of their original mass.

Spectra

The spectra of LBVs change with their photometric variations and their temperature variations. When the stars are visually faint the spectrum is typically that of an early-B supergiant. When the stars are visually bright their spectrum is that of an A-type supergiant. The studies of the spectral lines show that the atmospheres of LBVs are enriched in helium and nitrogen and depleted in carbon and oxygen, compared with normal stars.

The visual spectrum of LBVs is dominated by spectral lines with 'P Cygni profiles' consisting of an emission component and a blue-shifted absorption component. The wavelength shift of the absorption component is due to the Doppler effect and indicates an outflow velocity of several hundred km s^{-1}. The strength of the lines and the outflow velocity show that the LBVs are losing mass at a rate of about 2×10^{-5} to 6×10^{-5} solar masses per year. The mass loss rate of η Carinae is much higher and of the order of 10^{-3} solar masses per year.

Nebulae around LBVs

Almost all LBVs are surrounded by nebulae which are due to large eruptions in the past. The diameters of the nebulae are typically of the order of 0.2–2 parsec and the expansion velocity is between 25 and 100 km s^{-1}. The LBV η Carinae is an exception, as it shows different velocities from about 100 to 1000 km s^{-1} in different knots. The dynamical age $\tau_{\rm dyn}$ of LBV nebulae can be derived from their radius and outflow velocity: $\tau_{\rm dyn} = r_{\rm neb}/v$. The dynamical ages of the LBV nebulae are in the range 5000–50 000 years. The nebula of η Carinae has a dynamical age of 150 years and that of P Cygni has an age of 400 years, both in agreement with the observed historic large eruptions.

The evolutionary connection

The evolutionary stage of the LBVs can be derived from their location in the HERTZSPRUNG–RUSSELL DIAGRAM shown in figure 3. The stars make horizontal excursions in this diagram, due to the variations in radius and temperature at constant luminosity. The stars are close to the Humphreys–Davidson limit. This is the empirically determined luminosity upper limit in the Hertzsprung–Russell diagram. No stars brighter than this limit (except LBVs) have been found in the Milky Way or in other galaxies (see HIGH-LUMINOSITY STARS).

The location of the LBVs in the Hertzsprung–Russell diagram shows that the stars are in a post-main sequence evolutionary phase. The stars get their energy from helium fusion in the center. The increased helium and nitrogen abundance in their atmospheres is due to the fact that the original hydrogen-rich layers have been expelled, partly by mass loss when the star was still on the main sequence, and partly in the large eruptions. The helium and nitrogen enriched layers were formed by hydrogen fusion via the CNO cycle in the convective core of the star.

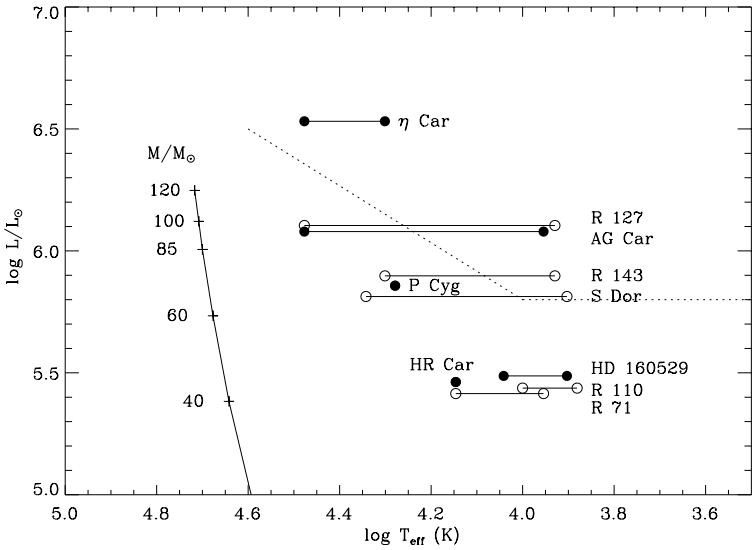

Figure 3. The location of the LBVs in the Hertzsprung–Russell diagram. Because the stars are variable they cover a range of effective temperatures. The full curve is the main sequence with the masses predicted by evolution theory indicated. The dashed line is the Humphreys–Davidson limit. Filled and open circles indicate LBVs in our Galaxy and in the Large Magellanic Cloud respectively.

The average duration of the LBV phase has been derived in a statistical way from a comparison between the numbers of LBVs and the numbers of other stars in the same range of initial masses. This shows that the LBV phase typically lasts a few times 10^4 years. With a typical mass loss rate of about 4×10^{-5} solar masses per year and the ejection of a few solar masses per large eruption every few thousand years, the total mass lost during the LBV phase can amount to a few tens of solar masses. The LBV phase ends when the star has ejected almost all of its hydrogen-rich material. The star then evolves into a hot helium-rich star, i.e. a Wolf–Rayet star.

Unsolved problems

Since the discovery of the large eruptions of P Cygni and η Carinae, their cause has been a great mystery. Several suggestions have been made:

(a) an instability due to a possibly fast rotating core,
(b) a geyser-type of instability due to the ionization of hydrogen in a critical layer,
(c) a 'strange-mode instability' due to the coupling of several pulsation modes, or
(d) large radiation pressure at a critical temperature zone in the star due to the iron opacity.

None of these theories can correctly predict the properties such as temperature, radius and luminosity of the stars for which the eruptions have been observed, nor the ejected amount of mass or the shapes of the nebulae.

The origin of the more common LBV variations with a size of a few magnitudes is also not understood. It is known that they are due to large variations in stellar radius by about a factor of ten or so. Originally it was assumed that the increase in radius is due to a sudden increase in the mass loss rate, which results in an opaque wind that makes the star appear to be larger. However, recent studies have shown that the winds of LBVs are not opaque and that the changes in radius must be due to some instability below the photosphere of the star. The instability is probably due to the large radiation pressure and the resulting small effective attraction in the outer layers of the star. The stellar layers are then only loosely bound to the star so that even small disturbances can have large effects. It has been suggested that the large eruptions are simply the extremes of the typical LBV variations.

Bibliography

The observations and properties of LBVs have been discussed in the review paper:

Humphreys R M and Davidson K 1994 The Luminous Blue Variables: Astrophysical Geysers *Publ. Astron. Soc. Pacific* **106** 1025

Reviews on specific properties of LBVs, their evolution and their variability can be found in the proceedings of conferences that were specially devoted to these stars:

Luna

Series of Soviet automated Moon missions launched 1959–76. Lunas 16, 20 and 24 were successful sample return missions. Lunas 17 and 21 carried the first automated Moon rovers, known as Lunokhods 1 and 2. (See also LUNOKHOD.) Luna 3 returned the first pictures of the lunar far side. Lunar 9 sent back the first pictures from the Moon's surface.

Lunar Orbiter

Series of five NASA Moon-orbiting spacecraft, launched 1966–67. Designed to map potential APOLLO landing sites. Perturbations in the orbit of Lunar Orbiter 1 provided the first data on lunar mass concentrations (mascons) and associated gravity anomalies. Used to create the first detailed lunar atlas, with spatial resolution down to 1 m.

Lunar Prospector

NASA Discovery mission, launched in January 1998. Designed to spend one year in orbit around the Moon. Carried a neutron spectrometer which gave strong indications of water ice in shadowed craters at both lunar poles. Also gave high resolution gravity data and returned information on the composition of the lunar crust. Lowered into a 30 km altitude orbit in January 1999 on completion of its primary mission. The extended mission was due to end in July 1999.

Lunar Transient Phenomenon (LTP)

A purported localized and short-lived change in the appearance of a feature on the surface of the Moon. LTPs tend to be reported by amateur observers of the Moon. They take various forms, including temporary colorations, usually red; bright flashes, visible especially in shadows or on the night side; extended cloudy patches; and obscurations of normally visible features.

Permanent changes to lunar features reported before the days of close-range photography from spacecraft are now discounted, being ascribed to deficiencies in mapping, observational error, or wishful thinking. A celebrated instance was the announcement in 1866 by Julius Schmidt that the crater Linné, described by previous observers as a small, deep pit, had vanished, to be replaced by a white patch. Modern photographs show Linné as a small crater of standard morphology, surrounded by light-colored ejecta.

Temporary changes reported more recently may be genuine, but they remain controversial. In 1958 the Soviet astronomer Nikolai Kozyrev spotted a red glow at the center of the crater Alphonsus, and obtained a spectrum which showed emissions of molecular carbon which he claimed was evidence of a volcanic emission. The observation was not corroborated, and evaluation was clouded by Cold War mistrust. Lack of corroboration remains a problem, as LTPs are usually seen by a single observer, and not photographed.

Unequivocal sightings of LTPs could be evidence that the Moon is not the geologically inert body it is generally held to be. There is a connection between LTPs and moonquakes—seismic tremors detected by instruments left on the Moon during the Apollo missions that originate near the crust/mantle boundary. Both phenomena are more common when the Moon is at perigee. The suggestion is that tidal flexing is triggering the release of gas or dust. It is possible that brief LTPs are caused by the impact of small meteorites.

Lund Observatory

Lund Observatory is part of Lund University, Lund, Sweden, active in astronomy since 1668. The past century featured stellar statistics (C V L Charlier) and (extra)galactic studies (K Lundmark, who produced a Milky-Way panorama in the 1950s). Current projects include stellar astrophysics, space astrometry, design of large optical and radio telescopes, and involvement in various international observatories.

Lunokhod

Two Soviet Moon rovers, the first automated roving vehicles to operate on another world. Operated from Earth by remote control. Carried stereo cameras, laser reflector, magnetometer, x-ray spectrometer and cosmic ray detector. Lunokhod 1 was launched on board Luna 17 in November 1970. It landed on Mare Imbrium and operated for 322 days, covering 10.5 km. Lunokhod 2 was launched on board Luna 21 in January 1973. It landed to the east of Mare Serenitatis and operated for four months, covering 37 km. (See also LUNA.)

Lupus

(the Wolf; abbrev. Lup, gen. Lupi; area 334 sq. deg.) A southern constellation which lies between Centaurus and Scorpius, and culminates at midnight in early May. It has long been associated with a wild animal, though the identification with a wolf dates from comparatively recent times. It is usually shown on early celestial charts as a wolf impaled on a thyrsus (staff) held by Chiron, the centaur, represented by the neighboring constellation of Centaurus. The brightest stars of Lupus were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A small but not inconspicuous constellation, overshadowed by Centaurus to the west, the brightest stars in Lupus are α Lupi, magnitude 2.3, β Lupi, magnitude 2.7, and γ Lupi, a very close binary with bluish-white (B2) components, magnitudes 3.5 and 3.6 (combined magnitude 2.8), separation 0.8″. There are ten other stars of magnitude 4.0 or brighter. Other interesting binaries include ξ Lupi, which has bluish-white (A3 and B9) components, magnitudes 5.1 and 5.6, separation 10.4″, and μ Lupi, a triple system consisting of a close pair of bluish-white (B7) components, magnitudes 5.0 and 5.1 (combined magnitude 4.3), separation 1.1″, and a third, bluish-white (A2) component, magnitude 7.2, separation 23″. Other interesting objects include NGC 5822, an open cluster of more than 100 stars between ninth and twelfth magnitude, and NGC 5986, a ninth-magnitude globular cluster.

Luyten, Willem Jacob (1899–1994)

American astronomer, worked at the University of Minnesota, determining proper motions of more than 120 000 stars, as a means of finding nearby or high-velocity stars, and determining their distances. He repeated the Palomar Observatory Sky Survey, building an automated computerized plate-measuring machine to compare it with the earlier survey, and thus determined the proper motions of 400 000 more. With these data he discovered the great majority of the white dwarfs known.

Lyman Alpha Absorption: The Damped Systems

Damped Lyα absorption systems are high column density gaseous objects that are detected in the spectra of background QUASARS on the basis of neutral hydrogen Lyα absorption lines broadened by radiation damping to large rest-frame equivalent widths. The damped Lyα absorption systems are of particular interest because (1) they can be identified to very large REDSHIFTS, (2) they dominate the mass density of neutral gas in the universe, containing at redshifts $z \approx 3$–5 a comoving mass density of neutral gas roughly comparable to the mass density of stars in present-day galaxies, and (3) they are predominantly neutral, allowing for heavy element abundances to be measured without the need of applying large ionization corrections. Many, most, or all damped Lyα absorption systems probably arise in the central parts of ordinary galaxies, although the exact relationship between damped Lyα absorption systems and galaxies is not yet firmly established.

It has been known since the late 1960s that the rest-frame ultraviolet spectra of HIGH-REDSHIFT QUASARS exhibit large numbers of discrete, isolated, narrow absorption lines. It was very quickly noted that the rate of incidence of these absorption lines is much larger at wavelengths shortward of the quasar Lyα emission lines than at wavelengths longward of the quasar Lyα emission lines. The reason is that almost all of the absorption lines at wavelengths shortward of the quasar Lyα emission lines are Lyα (or perhaps Lyβ, Lyγ, or higher-order Lyman transition) absorption lines produced by cosmologically distributed gaseous material that by chance intervenes along the lines of sight to the background quasars, at redshifts less than those of the background quasars. Collectively, the absorption lines that occur at wavelengths shortward of the quasar Lyα emission lines are known as the 'LYMAN ALPHA FOREST', because they give the impression of a thick forest of absorption that blankets the rest-frame ultraviolet spectra of high-redshift quasars.

The vast majority of the Lyα-forest absorption lines are of extremely low neutral hydrogen column density—typically $N = 10^{13}$–10^{15} cm^{-2}. But a very small minority of the Lyα-forest absorption lines are of much higher neutral hydrogen column density—ranging up to nearly $N = 10^{22}$ cm^{-2}. At neutral hydrogen column densities exceeding $N \approx 2 \times 10^{20}$ cm^{-2}, the Lyα absorption line profiles are optically thick in the radiation damping wings, and the Lyα absorption lines occur on the damped part of the curve of growth. For this reason, the highest neutral hydrogen column density Lyα-forest absorption lines are known as 'damped Lyα absorption lines', and the redshift complexes of absorption lines (consisting of Lyα and higher-order Lyman transitions as well as various heavy element transitions) associated with damped Lyα absorption lines are known as 'damped Lyα absorption systems'.

The column density threshold that distinguishes high column density damped Lyα absorption systems from lower column density Lyα-forest absorption systems is usually taken to be $N = 2 \times 10^{20}$ cm^{-2}. Although there is no particular physical significance that can be ascribed to this value, it is nevertheless a convenient choice because (1) absorption lines arising from such large neutral hydrogen column densities occur on the damped part of the curve of growth for any value of the velocity dispersion satisfying $\sigma < 100$ km s^{-1} (which in practice includes all quasar absorption line systems) and (2) it corresponds to the isophotal sensitivity threshold of the 21 cm neutral hydrogen survey of nearby galaxies conducted by Bosma in 1981, thus allowing for straightforward comparison of properties of damped Lyα absorption systems with properties of present-day galaxies. For present-day SPIRAL GALAXIES, for example, the Bosma radius (or the radius at which the gaseous disk reaches a neutral hydrogen column density threshold of $N = 2 \times 10^{20}$ cm^{-2}) extends to roughly 1.8 times the Holmberg radius (or the radius at which the stellar disk reaches the surface brightness of the night sky).

For Lyα absorption lines on the damped part of the curve of growth, the relationship between neutral hydrogen column density N and rest-frame Lyα equivalent width W is approximately given by

$$\frac{N}{2 \times 10^{20}\ \mathrm{cm}^{-2}} \approx \left(\frac{W}{10\ \text{Å}}\right)^2. \qquad (1)$$

A column density threshold $N = 2 \times 10^{20}$ cm^{-2} thus corresponds to a rest-frame Lyα equivalent width threshold $W = 10$ Å. In practice, damped Lyα absorption systems are identified on the basis of observed-frame equivalent width limited surveys for damped Lyα absorption lines. At high redshifts, even the lowest column density damped Lyα absorption systems give rise to Lyα absorption lines of observed-frame equivalent widths of many tens of Å and are easily detected in spectra of relatively low spectral resolution and signal-to-noise ratio. Roughly 1000 quasars have so far been surveyed for damped Lyα absorption lines, from which roughly 100 damped Lyα absorption systems have so far been identified, at redshifts ranging from $z \approx 0$ through 5.

At high redshifts, the observed rate of incidence of damped Lyα absorption systems is significantly larger than the predicted rate of incidence of damped Lyα absorption systems, under the assumptions that the absorption systems arise within the Bosma radii of spiral galaxies and that galaxies are fixed in comoving coordinates. The exact factor by which the observed rate of incidence exceeds the predicted rate of incidence depends on the choice of cosmological model, but could be as large as ≈ 2 for plausible cosmological parameters. This important result has been interpreted as suggesting that the gaseous disks of spiral galaxies were larger or more numerous in the past.

In more or less all cases that have so far been examined, the damped Lyα absorption systems exhibit

Copyright © Nature Publishing Group 2001

Dirac House, Temple Back, Bristol, BS1 6BE, UK

heavy element absorption lines from abundant low-ionization species, including transitions of C II, O I, Mg II, Si II and Fe II. In many (but not all) cases that have so far been examined, the damped Lyα absorption systems also exhibit heavy element absorption lines from abundant high-ionization species, including transitions of C IV and Si IV. The low- and high-ionization line profiles appear to be kinematically distinct, suggesting a multiple phase structure of the absorbing regions. In spectra of high spectral resolution and signal-to-noise ratio, damped Lyα absorption systems also exhibit heavy element absorption lines from low-abundance species, including transitions of Ti II, Cr II, Ni II and Zn II. These low-abundance species are of particular importance for measuring heavy element abundances.

Neutral gas content

The most important property of the damped Lyα absorption systems is that they dominate the mass density of neutral gas in the universe, containing at redshifts $z \approx 3$–5 a comoving mass density of neutral gas roughly comparable to the mass density of stars in present-day galaxies. Because stars form from neutral (rather than ionized) gas, this has the important implication that the damped Lyα absorption systems trace the bulk of material available for STAR FORMATION to high redshifts.

It is straightforward to show that the comoving mass density of neutral gas follows directly from observations of damped Lyα absorption systems, without regard to the geometry of the absorbing regions. Consider a population of absorption systems of some given neutral hydrogen column density N_0 and rate of incidence $n(z)$ per line of sight intercepted at redshift z over some redshift interval $\mathrm{d}z$ or cosmic time interval $\mathrm{d}t$. The proper mass density of neutral hydrogen contributed by the absorbers is obtained by taking the product $n(z)\,\mathrm{d}z$ (which gives the mean number of absorption systems intercepted by a line of sight over the redshift interval $\mathrm{d}z$), multiplying by the column density N_0 (which then gives the mean column density traversed by a line of sight over the redshift interval $\mathrm{d}z$), multiplying by the mass of the hydrogen atom m_{H} (which then gives the mean mass column density of a line of sight over the redshift interval $\mathrm{d}z$), and dividing by $c\,\mathrm{d}t$, where c is the speed of light.

The comoving mass density of neutral gas is then formed by multiplying by a factor $\mu = 1/(1-Y) \approx 0.33$ to allow for a helium abundance $Y = 0.25$ (by mass), dividing by $(1+z)^3$ to allow for the expansion of the universe, and dividing by the current critical density ρ_{crit} to yield a dimensionless mass density parameter Ω_{g}. The result is the comoving mass density of neutral gas in units of the current critical density.

In practice, the comoving mass density of neutral gas is determined not for absorption systems of some given neutral hydrogen column density N_0 but for absorption systems that span a range of neutral hydrogen column densities. The distribution of neutral hydrogen column densities is characterized by the column density distribution function $f(N)$, which is defined in such a way that the $f(N)\mathrm{d}N\mathrm{d}X$ is the number of absorption systems intercepted per line of sight with neutral hydrogen column density in the interval N to $N + \mathrm{d}N$ and in the absorption distance interval $\mathrm{d}X$. In terms of the column density distribution function, the mass density parameter is given by

$$\Omega_{\mathrm{g}} = \frac{H_0}{c}\frac{\mu m_{\mathrm{H}}}{\rho_{\mathrm{crit}}}\int_{N_{\mathrm{min}}}^{N_{\mathrm{max}}} N f(N)\mathrm{d}N \qquad (2)$$

where N_{min} and N_{max} are the minimum and maximum neutral hydrogen column density limits, respectively, and H_0 is the HUBBLE CONSTANT.

Over the range of neutral hydrogen column densities that have yet been measured, the column density distribution function of the damped Lyα absorption systems is well represented by a power-law form as

$$f(N) = BN^{-\beta} \qquad (3)$$

where the power-law index is measured to be $\beta \approx 1.6$. For such a shallow column density distribution function, the mass density parameter of equation (2) formally diverges as $N_{\mathrm{max}} \rightarrow \infty$, indicating that $f(N)$ must steepen at some sufficiently large neutral hydrogen column density. This steepening has not yet been measured. To obtain a convergent result, equation (2) is usually evaluated with N_{max} set equal to the largest observed neutral hydrogen column density, which at high redshifts approaches $N_{\mathrm{max}} = 10^{22}$ cm^{-2}. Uncertainty of the shape of the high column density end of the column density distribution function is the major uncertainty of Ω_{g}.

At redshifts $z \approx 3$–5, evaluation of equation (2) yields a mass density parameter $\Omega_{\mathrm{g}} \approx 2 \times 10^{-3}\ h^{-1}$, where h is the Hubble constant in units of 100 km s^{-1} Mpc^{-1} and where the exact value depends on the choice of cosmological model. This is equal to within observational uncertainty to the mass density parameter of stars in present-day galaxies, which is determined by multiplying the luminosity density of the nearby universe by the mean mass-to-light ratio of the stars that dominate the luminosities of galaxies. This very important result has been interpreted as indicating that high-redshift damped Lyα absorption systems are the progenitors of present-day galaxies, i.e. that the gaseous content of high-redshift damped Lyα absorption systems is gradually converted into the stellar content of present-day galaxies. It is unclear whether a systematic decrease in Ω_{g} with decreasing redshift—reflecting the conversion of gas into stars with time—has yet been measured.

Heavy element abundances

Another important property of the damped Lyα absorption systems is that they are predominantly neutral, allowing for heavy element abundances to be measured without the need of applying large ionization corrections. In particular, because the absorbing regions are self-shielded against ionizing radiation by high column density gas, neutral hydrogen and singly-ionized heavy elements (of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

elements with first ionization potentials less than one Rydberg) are the dominant ionization species. Gas-phase heavy element abundances are therefore obtained simply by dividing column densities of singly-ionized heavy element species by column densities of neutral hydrogen.

Absorption lines from low-abundance singly-ionized species, including transitions of Ti II, Cr II, Ni II and Zn II, are of particular importance because they are usually unsaturated (or only mildly saturated), allowing accurate column densities to be measured. For several reasons, most attention has so far been focused on transitions of Zn II and Cr II. In the interstellar medium of the Galaxy, Zn is not highly depleted onto dust grains, suggesting that the gas-phase abundance of Zn indicates the true abundance of Zn. In contrast, in the interstellar medium of the Galaxy, Cr is highly depleted onto dust grains, suggesting that the gas-phase abundance ratio of Zn to Cr is an indicator of the presence or absence of dust. Hence a single measurement of Zn II and Cr II column densities can simultaneously provide information about heavy element abundances and dust content.

At high redshifts ($z \approx 3$), Zn II and Cr II column densities of several dozen damped Lyα absorption systems have so far been measured. Results of these measurements indicate that the mean heavy element abundances are ≈ 0.1 times solar values, with a dispersion of a factor of two or three about this value. (Heavy element abundances of high-redshift damped Lyα absorption systems range from ≈ 0.01 times solar values to ≈ 0.5 times solar values.) The Zn to Cr abundance ratios suggest the presence of modest amounts of dust, although it is not exactly clear what values the undepleted abundances should take on—especially of Zn.

At low redshifts ($z < 1.6$), Zn II and Cr II column densities of only a few damped Lyα absorption systems have so far been measured. It is especially striking that there is no pronounced trend for heavy element abundances to increase with decreasing redshift, and in particular no trend for heavy element abundances to approach solar values at redshifts $z \approx 0$, as would be expected under scenarios of 'cosmic' chemical evolution due to the conversion of gas into stars. It is not yet clear how to interpret these results.

Relationship with galaxies

The most important outstanding issue regarding the damped Lyα absorption systems concerns their relationship with galaxies. Although the circumstantial evidence linking damped Lyα absorption systems with galaxies is substantial, attempts to observationally establish a direct relationship between damped Lyα absorption systems and galaxies have met with only limited success. Galaxies responsible for a small number of damped Lyα absorption systems have been identified, at both low and high redshifts. But galaxies responsible for other damped Lyα absorption systems have eluded identification, some despite very substantial effort. So while it is known that at least some damped Lyα absorption systems arise in galaxies, it is not known what range of properties (in terms, for example, of morphological type, luminosity, and surface brightness) are spanned by the absorbing galaxies, or even whether all damped Lyα absorption systems arise in galaxies.

Part of the difficulty is that the high neutral hydrogen column densities of damped Lyα absorption systems imply small impact parameters to the lines of sight, and it is difficult to identify faint galaxies at small angular separations to bright quasars. Recent advances in ADAPTIVE OPTICS technology may finally allow progress in this area.

Understanding the relationship between damped Lyα absorption systems and galaxies is probably the key to interpreting the heavy element abundance results. Measurements of damped Lyα absorption systems probe truly cosmic quantities in a way that measurements of few other classes of objects can do. The neutral hydrogen and heavy element content of the high-redshift universe—which is established on the basis of a uniform collection of measurements of damped Lyα absorption systems—is far more completely and homogeneously determined than the neutral hydrogen and heavy element content of the nearby universe—which is established on the basis of a diverse collection of visible- and radio-wavelength observations of gas, stars, and H II regions. Establishing the relationship between damped Lyα absorption systems and galaxies could well lead to surprises about where much of the neutral gas and heavy element content of galaxies reside.

Lyman Alpha Forest

The Lyman alpha forest is an absorption phenomenon seen in the spectra of high redshift QSOs and galaxies (figure 1). It is the only direct observational evidence we have of the existence and properties of the general INTERGALACTIC MEDIUM, and, as we have reason to believe, of most of the baryonic matter contents of the universe.

On its way to us the light of a bright, distant QSO passes through intervening intergalactic gas and through gas clouds associated with foreground galaxies. Absorption by the gas modifies the spectra of the background objects and imprints a record of the gas clouds' physical and chemical states on the observed background QSO and galaxy spectra. The whole arrangement is reminiscent of a giant cosmic slide projector, where a QSO plays the role of the light bulb, and the intervening gas clouds are the slides, changing the colors of the light source by absorbing parts of the (white) spectrum.

The name 'Lyman α forest' refers to the appearance of the optical QSO spectra, which show a forest of hundreds of sharp absorption lines, mostly from the neutral hydrogen (H I) Lyman α line, superimposed on the more smoothly varying QSO continuum (figure 2). Almost all the lines in the Lyman α forest correspond to the same atomic transition (which at 1215.67 Å is in the ultraviolet wavelength region). The phenomenon was first observed in the optical waveband ($\sim$ 4000–9000 Å) implying that the gas clouds causing the absorption are highly redshifted by the Hubble expansion. The absorption systems appear spread out into a 'forest' of lines because each line is redshifted by a different amount in proportion to the absorbing cloud's distance from us. The stronger ones among the absorption systems do show further spectral signatures in addition to their Lyα line: higher-order Lyman series lines begin to be detectable for absorption systems with Lyα close to saturation. Clouds with H I column densities larger than $N \sim 10^{17}$ cm^{-2} start showing a discontinuity due to continuous absorption at a rest frame wavelength 912 Å, beyond the limit of the Lyman series. These 'Lyman limit systems' occupy a column density regime where a gas cloud starts shielding itself against ionizing radiation from the outside. Clouds with even higher column densities ($N > 10^{19}$ cm^{-2}) exhibit the damping wings caused by the internal finite lifetime of the Lyα transition. The gas in these 'damped Lyα' systems (see LYMAN ALPHA ABSORPTION: THE DAMPED SYSTEMS) is almost completely self-shielded and mostly neutral. Most absorption systems with $N > 10^{14.5}$ cm^{-2} also show metal absorption lines (triply ionized carbon and silicon, and some other common elements and ionization stages). For that reason the higher column density systems are usually referred to as 'metal' or 'heavy element' systems. Here we are concerned only with the low column density gas, i.e., those absorption systems where the Lyα line is not saturated, which we will refer to as the Lyα forest proper. There definitely is an overlap between metal systems and Lyα forest systems in this restricted definition, but we have theoretical reasons to believe that there is a genuine dichotomy between intergalactic gas (represented by the Lyα forest), even if partly polluted by metals, and the invariably metal-enriched higher column density systems, thought to be related to galaxies.

Lyα forest absorption systems have now been observed from REDSHIFT zero (with UV satellites) up to the highest redshifts at which background light sources (QSOs and galaxies) can still be found (currently $z \sim$ 5–6).

The Gunn–Peterson effect: where does the absorption come from?

Lyα forest absorption in a QSO spectrum was predicted and first detected by Gunn and Peterson (1965). The basic idea is as follows: going back in time an increasing fraction of the total baryonic mass of the universe must be in the form of gas. The absorption cross-section of the Lyα line of neutral hydrogen is large enough that even if only a small fraction of the total mass of the universe were in the form of H I the redshifted Lyα lines should completely absorb a part of the spectrum of any background light source. The absorption should essentially assume the shape of an absorption trough in a QSO spectrum, extending blueward from the Lyα emission of the QSO. This particular absorption pattern is referred to in the literature as the 'Gunn–Peterson effect'. Gunn and Peterson did detect such a trough but the light of the QSO was not completely absorbed and there was some residual light left in the spectral region in question. The relative weakness of the absorption could mean two things: (a) there is little hydrogen left in intergalactic space and by the time the Lyα forest is observed most of the matter has already condensed into galaxies. Or (b) most of the hydrogen is not in neutral form, where it can produce Lyα absorption, but is fully ionized.

QSO surveys (see QUASISTELLAR OBJECTS: SURVEYS) later showed that the second possibility is more important: the combined ionizing radiation output from all known QSOs at high redshift amounts to a UV radiation field probably strong enough to keep most of the baryonic matter in the universe highly ionized—i.e., if the baryons are predominantly in the form of a more or less homogeneously distributed gas.

This conclusion is based on the assumption that the gas is in approximate photoionization equilibrium with the cosmic UV background field, i.e., the rate of recombinations of electrons with protons to form neutral hydrogen balances the rate of ionizations from the ground state of H I,

$$n_{\rm e} n_{\rm p} \alpha(T) = n_{\rm HI} \Gamma. \qquad (1)$$

Here Γ is the rate of photoionizations per neutral hydrogen atom, caused by the hydrogen-ionizing portion of the UV background field. The quantities $n_{\rm e}$, $n_{\rm HI}$ and $n_{\rm p}$ refer to the number densities of electrons, neutral hydrogen atoms, and protons (= ionized hydrogen), respectively.

Later observations of QSOs with higher spectral resolution (< a few hundred km s^{-1}) showed that

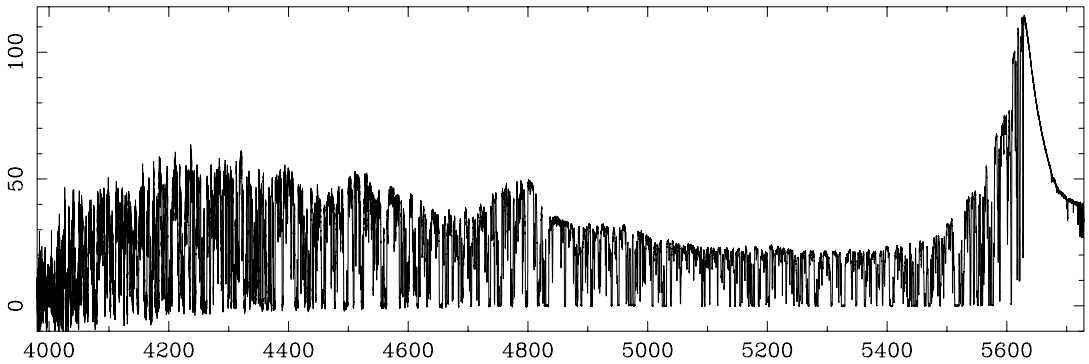

Figure 1. High resolution spectrum of the Lyα forest part of a redshift 3.63 QSO, taken with the HIRES spectrograph on the Keck 10 m telescope in Hawaii. The plot shows the flux of the QSO in arbitrary units versus the observed wavelength in units of Angstroms. The noise level can be judged from the longer wavelength wing of the broad, intrinsic Lyα emission line of the QSO (near 5650 Å). All of the ragged features are high redshift absorption lines. Most of the lines between the QSO's Lyα and Lyβ emission lines (the humps at 5650 and 4750 Å) are due to Lyα absorption by intervening gas. The actual rate of incidence of absorbers decreases towards shorter wavelengths (lower redshifts). Nevertheless, the line density increases to the blue because higher order absorption lines from the Lyman series appear and overlap randomly with Lyα lines of systems at lower redshift.

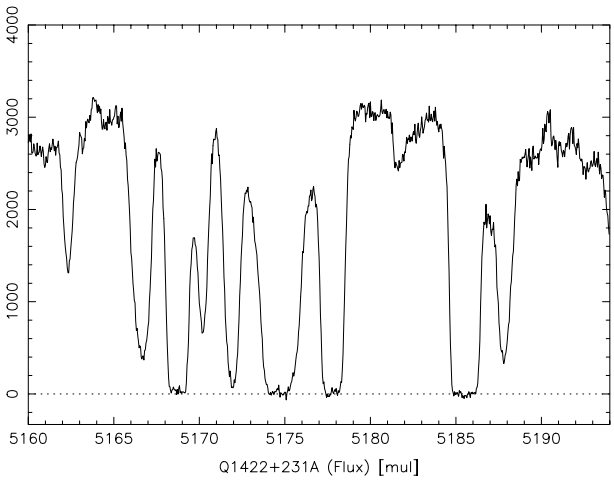

Figure 2. Detailed section of the previous spectrum. The image shows a number of absorption lines all corresponding to the neutral hydrogen (H I) Lyα 1215.67 Å transition. Lines close to saturation (= zero flux in the line center) have neutral hydrogen column density typically around $N \sim 10^{14.2}$ cm^{-2}, corresponding to a gas density enhanced by roughly an order of magnitude with respect to the mean density of the universe. The mean redshift of the stretch shown is $z = 3.248$. The spectral region extends over 3480 km s^{-1}. For a flat $\Omega = 1$ universe this corresponds to a spatial extent of approximately 9.6 h^{-1} Mpc along the line-of-sight.

what appeared as a smooth absorption 'trough' to earlier observers is in fact a ragged 'forest' of hundreds of individual absorption lines. In other words, the distribution of neutral hydrogen in the universe is inhomogeneous on scales down to the width of a typical Lyα line (see below). The degree of clumpiness appears magnified by the absorption pattern in the QSO spectra, because the residual (= unabsorbed) portion of the QSO's flux $I \propto e^{-\tau}$ depends exponentially on the Lyα optical depth τ, which itself depends almost quadratically on the gas density (or the electron density n_e; for a highly ionized gas at constant temperature). Thus small density fluctuations produce enhanced fluctuations in the optical depth. The Lyα forest absorption is observed in velocity space, and a convergent velocity field (e.g., a collapsing gas cloud) could also produce absorption 'lines'. Caustics in velocity space may form if several gas volume elements are moving at the same velocity relative to the observer. Indeed, if Lyα clouds are produced by gravitational collapse, both overdense regions and infall should contribute to an absorption line.

Spectroscopy of the Lyα line is an incredibly sensitive method to detect baryonic matter at any redshift. The photoionization cross section of neutral hydrogen is so large that an extremely tenuous gas at or below the mean density of the universe can be detected easily in absorption. The method of choice for studying the Lyα forest is optical high resolution spectroscopy, with a spectral resolution $\Delta\lambda/\lambda > 30\,000$ sufficient to resolve Lyα lines thermally broadened by the photoionization heating from the UV background. With 8 m class telescopes, a spectrum of a QSO suitable for further analysis of the Lyα forest absorption can be obtained within a few hours of observing time.

Basic observational properties of Lyα absorbers

Early models of Lyα absorption systems envisaged the absorption lines as arising from discrete 'clouds' of gas in intergalactic space. The clouds would be analoguous to galaxies, but the gas densities appeared too tenuous and too highly ionized to give rise to star formation. Moreover, the average clustering of the lines in velocity space was too weak for the clouds to be related directly to galaxies. Thus the gas giving rise to Lyα absorption systems came

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to be referred to as 'Lyα clouds' or 'intergalactic clouds', to distinguish it from gas associated with galaxies. It it is worth keeping in mind that even the term 'cloud' does already imply a prejudice as to the spatial distribution of the gas.

Before the advent of cosmogonies dominated by DARK MATTER (which could have supplied the gravitational attraction necessary to hold together the gas), it was thought more likely that the intergalactic clouds would be confined by the pressure of an even hotter and more tenuous intercloud medium. In this model, a cloud would be homogeneous, static or slowly expanding and, at least for some of its lifetime, in thermal photoionization equilibrium with the UV background.

Such an object has a simple observational signature in absorption. With only the intrinsic atomic line width of the Lyα transition and purely thermal motions contributing to the absorption line broadening, an individual line profile consists of a convolution of a Lorentzian resonance curve and a Maxwell–Boltzmann velocity distribution. The result is a so-called Voigt profile. Each such profile is fully specified by only 3 parameters: its position in velocity space (redshift), its column density (i.e. the number of neutral hydrogen atoms per unit area), and its line width (traditionally expressed in terms of the Doppler parameter $b = \sqrt{2}\sigma$, where σ is the standard deviation of the Maxwellian velocity distribution). The Lyα forest as a whole can then be characterized in terms of the distribution functions of these three quantities.

Column densities

Let us define $\mathrm{d}\mathcal{N}/\mathrm{d}N$ as the number of absorption lines, $\mathrm{d}\mathcal{N}$, per unit redshift with an H I column density between N and $N + \mathrm{d}N$. This function tells us how likely it is for our line-of-sight to a background QSO to intersect a cloud with a given H I column density N. Observationally, for H I column densities N spanning the amazing range from 10^{12} to 10^{22} cm^{-2} the distribution was found to be well-parametrized by a single power law in column density,

$$\frac{\mathrm{d}\mathcal{N}}{\mathrm{d}N} \propto N^{-1.5}. \qquad (2)$$

To give an idea of the normalization, there are hundreds of unsaturated lines ($N < 10^{14.5}$ cm^{-2}) per unit redshift but, typically, less than one damped Lyα system ($N > 10^{21}$ cm^{-2}). For comparison, a QSO spectrum at redshift 3 covers $\Delta z \sim 0.6$ of the Lyα forest (between the QSO redshift and the redshift corresponding to the onset of the Lyβ series).

The distribution of absorption systems in velocity space

We may consider two limiting cases. (a) The distribution of absorbers over very large (Gigaparsec) scales; this is is equivalent to a distribution in time or redshift, as the universe changes considerably during the time it takes a light ray to traverse a Gigaparsec. (b) The distribution on small (Megaparsec) scales; here we expect local astrophysics (gravity, galactic outflows, nearby sources of ionizing radiation) to affect the clustering of the lines in velocity space.

(a) The evolution of the number of absorption lines $\mathcal{N}$ with time or redshift z (and with a column density above a certain threshold) traditionally has been approximated by a power-law in $(1 + z)$,

$$\frac{\mathrm{d}\mathcal{N}}{\mathrm{d}z} \propto (1 + z)^{\gamma}. \qquad (3)$$

For a universe where Lyα clouds are non-evolving, $0 < \gamma < 1/2$, depending on the cosmological model. With the observational baseline now extending from the local universe out to redshift five it has become clear that γ is not constant with time. In the local universe ($z \sim 0$) up to redshift ~ 1.5, γ is consistent with the above no-evolution values. However, beyond redshift $z \sim 1.5$ there is a sharp increase in the number of absorption lines, with γ rising up to a value $\gamma \sim 5$ by redshift $z \sim 4$.

There is a general trend for the number of absorption lines to increase with redshift, but in any individual QSO spectrum there is a relative lack of absorption systems close to the redshift of the QSO. This so-called 'proximity effect' has been ascribed to the ionizing radiation produced by the QSO itself, which reduces the neutral hydrogen fraction for gas close to the QSO. The effect can be used to measure the strength of the ionizing background radiation: consider a point at a distance from the QSO, where the number of Lyα systems has declined by half as compared to the average line density in the Lyα forest. At this point the intensity of ionizing radiation from the QSO must equal the intensity of the general UV background. Knowing the luminosity of the QSO we can compute the flux at that point, and thus, the intensity of the ionizing background. This method, though fraught with many uncertainties, has yielded the first measurement of the ionizing UV background.

(b) The small-scale distribution of absorption lines in velocity space along the line-of-sight, often referred to as 'clustering', has yielded only limited information about the nature of the Lyα forest systems. If the clustering is measured with the same methods used for galaxy surveys, namely by applying the two-point-correlation function to discrete absorption lines, there is a significant signal only for the highest column density ($N > 10^{15}$ cm^{-2}) systems. These stronger absorption lines are invariably accompanied by absorption from heavier elements (carbon, silicon, oxygen, iron in various stages of ionization), so the high column density clouds must in some way be more closely associated with galaxies as the production sites of the metals. The observed stronger clustering of this gas may arise when gas clouds move in a galactic gravitational potential well, or they may just reflect stellar ejecta in the interstellar medium of those galaxies. However, most of the Lyα forest consists of weaker lines, which do not cluster along the line-of-sight appreciably. Gas densities inferred for the weaker lines are likely to be much lower than for galaxies. If gravity is

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the main structure forming agent it is not very surprising that lower density regions are clustered more weakly.

Searches for voids in the Lyα forest similar to those seen in the spatial distribution of galaxies have been equally unsuccessful, implying again that most Lyα absorption systems are more homogeneously distributed in space than galaxies.

Absorption line widths

The width of an absorption line is a measure of the total velocity distribution in the gas. Both microscopic (thermal motion) and macroscopic processes (turbulence, bulk flows, broadening of an extended object by the Hubble expansion) may contribute to the line profile. Without an *a priori* theory about line formation the total width b of the line profile can only be used as an upper limit to the width due to any individual process. As an example, the Doppler parameter of a thermally broadened absorption line with an additional Gaussian contribution describing turbulence in the gas is given exactly by

$$b = \sqrt{\frac{2kT}{m} + b_{\rm turb}^2} \tag{4}$$

where T is the temperature of the gas, k is Boltzmann's constant, m is the mass of the hydrogen atom, and $b_{\rm turb}$ is the turbulent contribution to the Doppler parameter.

At redshift $\sim$ 3 observations show the Doppler parameters b to be distributed according to a Gaussian with a mean $\overline{b}$ between 25 and 30 km s^{-1}, and a cutoff $b_{\rm cut}$ below about 19 km s^{-1}, i.e.,

$$\frac{{\rm d}\mathcal{N}}{{\rm d}b} \propto \exp\left(\frac{(\overline{b}-b)^2}{2\sigma_{\rm b}^2}\right) \quad \text{for } b \geq b_{\rm cut} \tag{5}$$

$$= 0 \qquad \text{for } b < b_{\rm cut}, \tag{6}$$

This analytic relation gives a good description of the actual distribution. Doppler parameters below the cutoff are very rare, but there appears to be a weak non-Gaussian tail towards larger Doppler parameters. The parameters of the distribution quoted vary somewhat among different researchers, but there is agreement in that the line widths at higher redshifts (3.5–4.5) are lower by perhaps 25% .

If the broadening were purely thermal then typical b values as discussed above would correspond to upper limits on the gas temperature $T \leq 3$–5×10^4 K.

Size, density, and ionization state of Lyα clouds

Absorption line studies suffer from the limitation that in general only one-dimensional information along the line-of-sight is available. From the absorption line itself we measure the temperature and column density of the gas, and from observations of the QSO luminosity function we can compute an estimate of the ionizing background radiation, but to obtain the density and the ionized fraction of the gas an additional independent estimate of the size of the absorbing gas cloud is needed.

Observations of close lines-of-sight to groups of QSOs or to multiple images of gravitationally lensed QSOs can restore to some degree the missing second dimension and provide a measurement of the cloud sizes, at least as projected in the plane of the sky. Imagine that we had two lines of sight with a known separation. For Lyα 'clouds' with a given size, some of the clouds will intersect both lines-of-sight, others only one of them. In a statistical sense, the typical size of Lyα forest absorbers can be determined from the numbers of 'hits' and 'misses', i.e., from knowing how often an absorption system seen in one of the lines-of-sight also appears in the second one. Such estimates have yielded astonishingly large transverse sizes on the order of 0.1–1 Mpc proper separation. These sizes enable us to compute rough estimates of the ionization fraction and density of the gas.

Assuming that the neutral fraction x of hydrogen is determined by photoionization equilibrium (cf equation (1)), we have

$$x = 3.9 \times 10^{-6} \left(\frac{T}{3\times10^4}\right)^{-0.35} \left(\frac{I}{10^{-21}}\right)^{-0.5} \times \left(\frac{N}{10^{14}}\right)^{0.5} \left(\frac{D}{100\ {\rm kpc}}\right)^{-0.5}, \tag{7}$$

where T is the gas temperature in K, I is the intensity of the ionizing UV background in units of ergs Hz^{-1} sr^{-1} s^{-1} cm^{-2}, N the H I column density in cm^{-2}, and D the thickness of the cloud (or the path length of our line of sight through it).

Likewise, the total number density of the gas (the number of protons per cm^3) is given by

$$n = x^{-1} N D^{-1} = 8.3 \times 10^{-5} \left(\frac{T}{3\times10^4}\right)^{0.35} \left(\frac{I}{10^{-21}}\right)^{0.5} \times \left(\frac{N}{10^{14}}\right)^{0.5} \left(\frac{D}{100\ {\rm kpc}}\right)^{-0.5}. \tag{8}$$

This is about four orders of magnitude less dense than the gas in the disk of our Galaxy. Even if the clouds are not spherical but flattened (so they would appear more extended across than along the line-of-sight) the conclusion is inescapable that the gas is highly ionized and the density in the typical cloud is within a factor of a few from the mean density of the universe, far less than the average density in a galaxy.

The intergalactic medium as a cosmic fluid

So far we have used only simple astrophysical arguments to infer the basic physical properties of the Lyα absorbers, without explicit reference to a model of structure formation. The decomposition into Voigt profiles had originally been justified by the assumption that Lyα absorption systems are discrete, pressure-confined gas clouds in hydrostatic, thermal and ionization equilibrium, floating in intergalactic space. This picture provided an analytically tractable model which made a host of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

observationally testable predictions, several of which unfortunately contradicted the observational evidence. For example, the large range in column densities observed, and the evolution of the number of absorption systems with redshift are difficult to reproduce in that model. Moreover, observations of the spectral shape of the cosmic microwave background radiation with the COBE satellite have provided arguments against the existence of a hot intercloud medium necessary to provide the confinement pressure for the Lyα clouds.

The pressure-confinement model finally fell from grace because of its lack of a convincing theory of the formation of the cloudlets, and the rise (in popularity) of structure formation cosmogonies dominated by the presence of large amounts of weakly interacting dark matter. The gravitational collapse of dark matter would have trapped large amounts of baryonic gas as well. The most popular, cold dark matter (CDM) structure formation scenario predicts a large abundance of collapsed CDM halos with individual masses too small to form stars and turn into galaxies. Warm photoionized intergalactic gas sinks into these 'mini'-halos or accretes onto dark matter filaments and sheets. The thermal gas pressure prevents the gas from further collapse; relatively stable gaseous configurations are formed. These structures are visible only in absorption since there are no stars which could produce any light.

A breakthrough in cosmology occured in the early 1990s when hydrodynamic cosmological simulations became available. As far as the comparison with data is concerned the hydrodynamics simulations represent an advance over pure dark matter (so-called N-body) simulations, as they attempt to directly predict observable astrophysical quantities. The hydro-codes include, in a simplified way, gas dynamics, elementary radiative processes, heating and cooling, and some schematic stellar feedback, all of which are essential to an understanding of the formation of structure for ordinary (baryonic) matter like galaxies, stars and intergalactic gas clouds. The ultimate hope of the hydro-simulations is to reproduce realistic galaxies, but at the current level of detail and spatial resolution possible the intergalactic medium with its simple physics is perhaps the most promising target for quantitative modelling.

The cosmic web

If the underlying cosmological picture (a universe dominated by cold dark matter) is correct, then the hydro-simulations are telling us that the spatial distribution and physical state of the Lyα forest gas is more complex than previously thought. The gas is arranged in filaments and sheets, in what has been called the 'cosmic web', closely tracing the dark matter distribution on large scales (figure 3). Low column density absorption systems ($N \lesssim 10^{14}$ cm^{-2}) are associated with sheet-like structures or pancakes of gas (length scale $\sim$ a few hundred kpc to 1 Mpc proper). The gas accretes through weak shocks (developing a double humped temperature profile), and

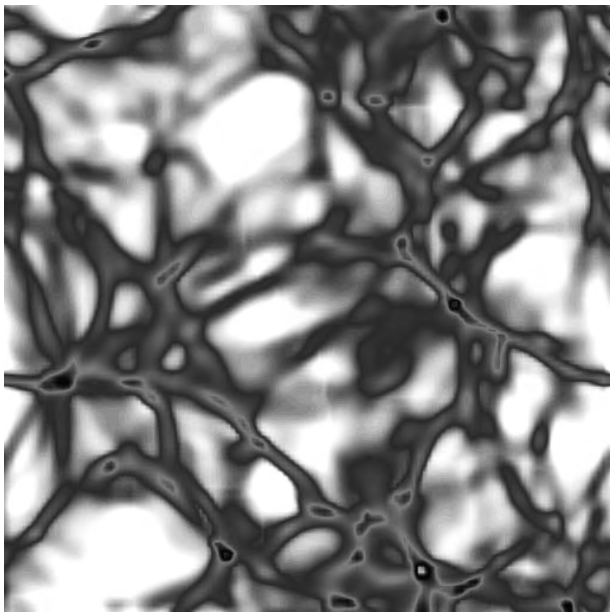

Figure 3. Cosmological hydro-simulation: projection of the baryonic density distribution in a simulated box at $z = 3$ (same spatial extent as for figure 2) showing the 'cosmic web' filamentary structure of the Lyα forest (image courtesy Michael Norman, University of Illinois).

settles in a dense, central cooling layer, presumably to form stars in some of the denser regions. At the lowest column densities gas remains unshocked and just bounces back because of the hydrostatic pressure. The gas is partly confined by dark matter gravity and partly by ram-pressure. Higher column density clouds arise in more filamentary structures, with column density contours of $N \sim 10^{14}$ cm^{-2} extending continuously and at relatively constant thickness ($\sim$ 40–100 kpc proper) over Mpc distances. With increasing column density the absorber geometry becomes rounder; column density contours at $N \gtrsim 10^{16}$cm^{-2} invariably are spherical. Such absorbers more closely correspond to the aforementioned minihalos; there the enclosed gas column is high enough to make the absorption system appear as a Lyman limit or damped Lyα system. Looking at the higher column density, optically thick gas on scales of several Mpc one gets a somewhat different impression of chains of mini- or larger halos, lining up like pearls on a string, quite similar to the structure seen in N-body simulations of the dark matter distribution. To produce as much absorption as observed, a large fraction of all baryons (80–90%) is required to reside in the low column density Lyα forest, mostly in the column density range $10^{14} < N < 10^{15.5}$ cm^{-2}.

In general this theoretical picture very well reproduces the observational properties mentioned earlier. The column density distribution is in excellent agreement, as are the large transverse sizes measured in projection, and the clustering along the line-of-sight. In this model the rapid evolution of the number of the absorption systems

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with redshift is largely a consequence of the expansion of the gas with the Hubble flow. The statistical distribution of the flux level $I = e^{-\tau}$ in the Lyα forest is extremely well matched by these models, as can be seen from a comparison of the observed distribution with one from a simulated ΛCDM universe (figure 4). The spatial correlations as evident from the flux power-spectrum are equally well reproduced. The most complex piece of observational information, the distribution of Doppler parameters is qualitatively understood, but as it depends on a variety of initial conditions (epoch of reionization, baryonic density of the universe, cosmological model) and possible stellar energy feedback, several of these parameters need to be tuned carefully to get acceptable quantitative agreement.

Perhaps most importantly, the successes of the hydro-models show that the majority of the Lyα absorbers are consistent with being low density condensations formed by gravitational collapse of the intergalactic medium. In this picture the gas seen as Lyα forest *is* the original reservoir of matter from which galaxies are condensing.

Conversely, the success in reproducing the observations of the Lyα forest provides perhaps the best observational evidence for *hierarchical* structure formation we have to date.

Cosmology with the Lyα forest

Most of the intergalactic gas observed at high redshift has experienced only mild gravitational collapse. A typical region of space has undergone little processing other than heating by photoionization and compression, in competition with adiabatic cooling by the Hubble expansion. It turns out that the weaker, unsaturated absorption lines ($N < 10^{14}$ cm^{-2}) are still on or near the linear regime of gravitational collapse. Even for lines close to saturation the overdensities with respect to the mean density of the universe are less than about a factor $\delta \sim 10$–15. On spatial scales on the order of one Mpc and larger where the thermal pressure of the gas is not important the intergalactic medium traces the underlying mass distribution much more closely than the stellar light of galaxies observed in emission. This fact and the simple astrophysics involved should make the intergalactic medium an ideal cosmological laboratory.

Recently there have been various attempts at tapping the cosmological potential of the Lyα forest. The link between the observable appearance of the Lyα forest and the various cosmological input parameters can be described approximately by the Gunn–Peterson relation for the H I optical depth τ, generalized to include an inhomogenous density and velocity field. As long as the gas is highly ionized and in photoionization equilibrium (not necessarily thermal equilibrium), and the gas is unshocked, the optical depth for Lyα absorption at redshift z is proportional to

$$\tau(z) \propto \frac{(\Omega_b h_{50}^2)^2}{\Gamma} \left(\frac{H(0)}{h_{50} H(z)}\right) T^{-0.7} \times \left(\frac{\rho}{\overline{\rho}}\right)^{\alpha} (1+z)^6 \left(1 + \frac{\mathrm{d}v_{\mathrm{pec}}}{H(z)\mathrm{d}r}\right)^{-1} \quad (9)$$

This equation relates the optical depth to the mean baryonic density (in gas) in units of the critical density, Ω_b, the Hubble constant at redshift z, $H(z)$, the average gas temperature T, the proper baryon density ρ, the photoionization rate Γ, and the gradient of the local peculiar velocity $\mathrm{d}v_{\mathrm{pec}}/\mathrm{d}r$ along the line-of-sight. A further convolution with a Voigt profile is necessary to include the proper thermal velocity broadening. The exponent α ($\alpha = 2$ for an isothermal gas) takes account of the fact that in denser regions of the universe the gas is typically warmer because it is more effectively heated by photoionization, but α also depends on the reionization history of the gas and the amount of adiabatic expansion/compression. Values of $\alpha \approx 1.6$–1.8 are given in the literature.

To turn this relation into a complete description of the observed Lyα forest, cosmology has to predict the cosmic density and velocity fields, the fraction of the closure density in the form of gas, the equation of state of the intergalactic medium, and the ionizing radiation field. Measuring cosmological parameters then boils down to creating Lyα forest spectra according to a given cosmological prescription, and iterating with varying input parameters until good agreement between observed and predicted properties is obtained. At the time of writing these techniques are just beginning to be explored, but it has become obvious that there are at least three main areas to benefit from such studies.

From equation (9) the optical depth is directly proportional to the ratio $(\Omega_b h_{50}^2)^2/\Gamma$. In other words, a higher density produces stronger absorption, but a higher photoionization rate reduces the neutral fraction of the gas and decreases the absorption. With a suitable hypothesis for or an independent measurement of the photoionization rate Γ (e.g. estimating the density of ionizing photons from QSO surveys) the baryon density Ω_b of the universe may be constrained.

The 'equation of state' of the intergalactic medium, as the statistical distribution of the gas volume elements in temperature-density ($T - \rho$) space has become known, has a more complex and subtle influence on the optical depth distribution: a change in the slope $\mathrm{d}T/\mathrm{d}\rho$ changes the value of the temperature of a given volume element and thus the recombination coefficient $\alpha(T)$, the neutral fraction and column density, and the absorption line width. It appears that the distribution of the Lyα forest lines in Doppler parameter–column density ($b - N$) space is a distorted map of the density–temperature relation, and can be used to constrain the latter. $T(\rho)$, in turn, contains information on the epoch of reionization and reheating and on the sources of ionizing radiation.

Finally, it is clear that the fluctuation properties (amplitude, spatial correlation) of the density ρ and peculiar velocity v_{pec} fields propagate through to the optical depth (cf equation (9)). At least in the regime where the Lyα lines are strong enough to be detected but not yet too strong to be saturated, the spectra provide a record of the initial conditions of gravitational structure

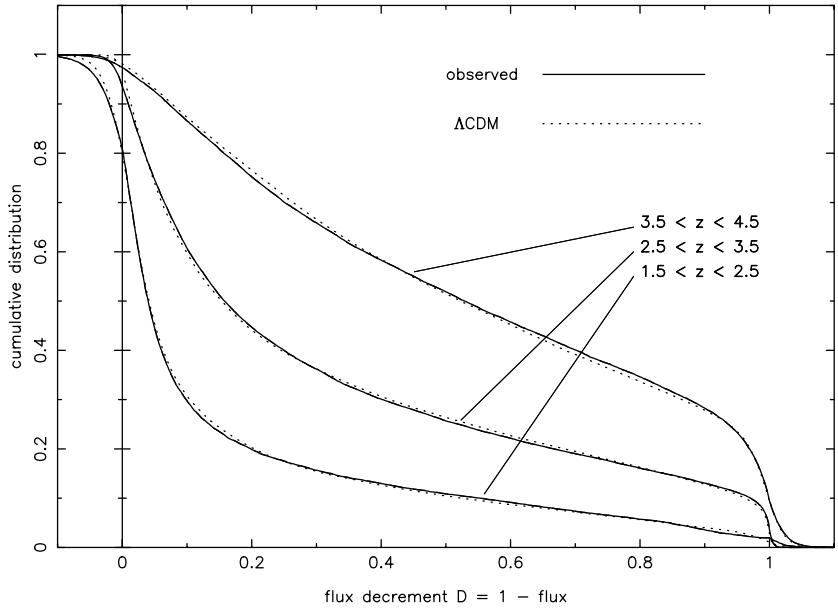

Figure 4. Observed and simulated statistical distributions of the absorbed flux level in the Lyα forest, for three different mean redshifts. The solid lines show the distribution for a sample of QSOs observed with the Keck telescope, the dotted lines are from a simulation of a ΛCDM universe (performed by Renyue Cen *et al* at Princeton University). The good agreement in the shape of the distributions lends observational support to the Lyα forest being a by-product of hierarchical structure formation.

formation. In principle the Lyα forest spectra can be inverted to provide a measurement of the power spectrum shape and amplitude of the initial fluctuations.

The helium Lyα forest

We conclude with a glance at one of the most intriguing new topics of research, the Lyα forest absorption due to singly ionized helium (He II). The He II forest has only recently become acessible as the transition is in the far ultraviolet (304 Å) and even if redshifted out to $z \sim 3$ still needs to be observed with a UV spectrograph from space. In addition, it is very difficult to find a QSO with its UV continuum intact, as the Lyman limit continuum absorption from higher redshift systems tends to obliterate the far UV in most QSOs. Nevertheless, there are potentially big scientific rewards to be gained: (1) since He II and H I have different ionization potentials, looking at the ratio of the column densities from their respective Lyα forests one can constrain the shape of the UV spectrum ionizing the two species. (2) Helium and hydrogen atomic masses differ sufficiently that a comparison of the Doppler parameters of both can measure the amount of non-thermal line broadening. (3) The first observations of He II forests are showing that He II ionization appears to be patchy and not fully developed by redshift 3–4. This observation could help us to understand how and when the universe was first ionized.

There are many other topics related to the rapidly growing field of QSO absorption lines for which we refer the interested reader to the literature given below (see also QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES; INTRINSIC AGN ABSORPTION LINES). These include metal absorption systems in general, and the correspondence between absorption systems and various galactic or interstellar environments, as seen in local galaxies. Damped Lyα systems, the absorbers most relevant to high redshift galaxy formation, are treated in the separate article LYMAN ALPHA ABSORPTION: THE DAMPED SYSTEMS.

Bibliography

Reviews of the subject at a level accessible to students, and detailed references to the literature are given in

Weymann R J, Carswell R F and Smith M G 1981 Absorption lines in the spectra of quasistellar objects *Ann. Rev. Astron. Astrophys.* **19** 41

Rauch M 1998 The Lyman Alpha Forest in the spectra of QSOs *Ann. Rev. Astron. Astrophys.* **36** 267

The scientific literature on the subject begins with the first measurement of the Gunn–Peterson effect, published as

Gunn J E and Peterson B A 1965 On the density of neutral hydrogen in intergalactic space *Astrophys. J.* **142** 1633

A number of conference proceedings give very useful overviews at a somewhat more technical level than the reviews; they are indispensible as guides to the many topics related to QSO absorption lines which could not be treated here:

Lynx

(the Lynx; abbrev. Lyn, gen. Lyncis; area 545 sq. deg.) A northern constellation which lies between Ursa Major and Auriga, and culminates at midnight in late January. It was introduced by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* of 1687. An inconspicuous constellation, Hevelius (who distrusted telescopic sights for stellar observations) called it Lynx because, he wrote, one would have to be lynx-eyed to see it!

The brightest stars in Lynx are α Lyncis, magnitude 3.1, 38 Lyncis, a binary with bluish-white (A3 and A4) components, magnitudes 3.9 and 6.6, separation 2.7″, the latter of which has an unseen companion, and HR 3579, magnitude 4.0. Another interesting multiple star system is 12 Lyncis, which consists of a close pair of bluish-white (A2) components, magnitudes 5.4 and 6.0, separation 1.7″, period about 700 years, and a third component, magnitude 7.1, separation 8″. Other interesting objects include NGC 2419, a tenth-magnitude globular cluster remarkable for its remoteness from the halo of globular clusters surrounding the Galaxy (its being further away than the Magellanic Clouds), and NGC 2683, a tenth-magnitude spiral galaxy.

Lyot, Bernard Ferdinand (1897–1952)

Astronomer, born in Paris, worked at the Paris Observatory at Meudon, invented the coronagraph, a device that creates an artificial eclipse in a telescope and allows the Sun's corona to be observed at any time. With it he recorded the spectrum of the corona in new detail, and the first time-lapse pictures of solar prominences. Invented the *Lyot filter*, a birefringent interference filter made of alternating layers of polaroid and calcite plates. With a photoelectric polarimeter of unprecedented accuracy, he also pioneered the astronomical study of the polarization of light reflected from the surface of the Moon and of the planets, finding that the lunar surface behaves like volcanic dust and that Mars has sandstorms. Lyot's name is commemorated in the *Télescope National Bernard Lyot* of the Pic du Midi Observatory in the Pyrenees.

Lyra

(the Lyre; abbrev. Lyr, gen. Lyrae; area 286 sq. deg.) A northern constellation which lies between Hercules and Cygnus, and culminates at midnight in early July. It is an ancient constellation pattern, which was associated with an eagle or vulture in the Indian subcontinent and Arab countries, and with the mythical lyre invented by Hermes and given by Apollo to Orpheus in ancient Greece. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small but conspicuous constellation, Lyra is easily recognized by virtue of α Lyrae (Vega), which at magnitude 0.0 is the fifth brightest star in the sky and from northern temperate latitudes is almost immediately overhead on summer evenings, when together with α Aquilae (Altair) and α Cygni (Deneb) it makes up the asterism of the Summer Triangle. Other bright stars include γ Lyrae (Sulafat), magnitude 3.3, and β Lyrae (Sheliak), a multiple system consisting of an eclipsing binary (range 3.25–4.36, period 12.91 days) and two widely separated fainter stars, magnitudes 7.2 and 9.9v, separations 46″ and 86″, the brighter component of which also has an unseen companion. There are no other stars brighter than fourth magnitude. Other interesting stars include ε Lyrae, the so-called 'Double Double', which consists of two close binaries, ε^1, with bluish-white (A4 and F1) components, magnitudes 5.1 and 6.0, separation 2.5″, and ε^2, also with bluish-white (A8 and F0) components, magnitudes 5.1 and 5.4, separation 2.3″, themselves separated by 209″, and RR Lyrae, the brightest known member of a class of pulsating variables (range 7.06–8.12, period 0.57 day).

Other interesting objects in Lyra include M57 (NGC 6720, the Ring Nebula), a ninth-magnitude planetary nebula, and M56 (NGC 6779), an eighth-magnitude globular cluster.

The Lyrid meteor shower (sometimes called the April Lyrids to distinguish it from a lesser shower that occurs in June) appears to radiate from a point to the south-west of Vega.

See also: Epsilon Lyrae, Lyrids, Ring Nebula, RR Lyrae stars.

Lyrids

A meteor shower that takes place in April, sometimes known as the *April Lyrids*. The radiant lies in the constellation Lyra, close to the border with Hercules, near the star Vega. There are occasional outbursts, most recently in 1982, where the usual peak zenithal hourly rate of 10–15 increases to 100 or more. The parent comet, C/1861 G1 Thatcher, has the longest period (415 years) of any comet known to be associated with a meteor shower. Its high orbital inclination of 80° means that the meteor stream is little affected by planetary perturbations, and Lyrid activity therefore shows a long-term constancy.

See also: meteor shower.

Mästlin, Michael (1550–1631)

Born in Göppingen, Germany, taught by, and an assistant to, PETER APIAN, became professor of astronomy at Tubingen, where he taught the Copernican as well as the Ptolemaic system. He taught KEPLER, and helped him to publish his first work, *Mysterium Cosmographicum* (1596). He made his own astronomical instruments. He was one of the first three or four astronomers to see in Cassiopeia what is now called TYCHO's supernova, the new star of 1572. He determined that it had no motion over the night by holding a thread between two stars, with the nova on the same line, and was not therefore a comet.

Möbius, August Ferdinand (1790–1868)

Mathematician, born in Schulpforta, Saxony (now Germany), studied astronomy under GAUSS, and wrote his doctoral thesis on 'The occultation of fixed stars by planets'. Became professor of astronomy at Leipzig, rebuilt its observatory, and wrote on astronomy and celestial mechanics, this work being overshadowed by his imaginative mathematical work on mapmaking and analytical geometry (eponymous mathematical items include a Möbius net, a Möbius function, and the one-sided surface called the Möbius strip).

Mégantic Astronomical Observatory

The Mont Mégantic Observatory is operated by the Université de Montréal. It is located 250 km east of Montreal, on the summit of the highest mountain in Quebec, at an altitude of 1111 m. Its 1.6 m diameter Ritchey–Chrétien telescope is used for observations at visible and near-infrared wavelengths.

The telescope is used for imaging, spectroscopy and polarimetry at visible wavelengths. An infrared camera is also available, though it is often 'borrowed' by astronomers who observe with the CANADA–FRANCE–HAWAII TELESCOPE. There is also a meteorological station on the site.

M1

M1 is the famous CRAB NEBULA in Taurus, one of the most celebrated objects in the sky, the remains of a supernova seen to explode in AD 1054. Messier stumbled across it in 1758 while following a comet that passed through Taurus; he described the nebula as 'elongated like the flame of a candle'. However, it had already been discovered by an English astronomer, John Bevis, in 1731. M1 lies just over a degree northwest of Zeta Tauri and is an eighth-magnitude patch measuring about 8 by 6 arc minutes in apparent size; its true dimensions are about 11 by 7.5 light-years. Its popular name comes from a description by Lord Rosse, who observed filaments extending from it like the pincers of a crab. At its center is a sixteenth-magnitude neutron star, the Crab pulsar; this is the compressed core of the star that exploded. M1 lies about 6500 light-years away.

M10

M10 is a globular cluster in the constellation Ophiuchus (the star 30 Ophiuchi is just 1 degree to the east-southeast). It was discovered by Messier who did not resolve any stars because it is fairly compressed. It has a diameter of 70 light-years but its bright core is only half that size. Its visual brighness is 6.7 mag and it displays a slight flattening (ellipticity E1). The distance to the Sun is about 13 400 light-years (with some sources quoting values up to 16 300 light-years).

M10 was investigated for variable stars by Baade but only contains three to four of them and has hence not been investigated in great detail by astronomers.

M100

M100 is one of the largest spiral galaxies in the Virgo Cluster, its true size being similar to that of the Andromeda Galaxy, M31. It lies in Coma Berenices, completing a triangle around the star 6 Comae Berenices with M98 and M99, all of which were discovered by Mechain on the same fruitful night in March 1781. Although M100 is cataloged as of ninth magnitude, roughly twice as bright as M98 and M99, it is no easier to see visually than those galaxies because its light is spread over a greater area, resulting in a low surface brightness. It is classified as type Sc. Lord Rosse was the first to see its spiral arms, in 1850. Allan Sandage has concluded that the two main arms are about 3 000 light-years thick, twice the thickness of the arms in our own Galaxy. An asymmetry in the shape of the spiral arms seems to be to gravitational disturbance by a nearby dwarf elliptical galaxy, NGC 4322, in a smaller-scale version of the interaction between the Whirlpool Galaxy, M51, and its companion. Four supernovae have been seen here, in 1901, 1914, 1959 and 1979. The 1979 event was unusually bright, reaching a peak of eleventh magnitude; the following year, radio emission from its remnant was picked up by astronomers using the Very Large Array, the first time an extragalactic supernova had been detected at radio wavelengths. Infrared images of M100 taken in 1995 showed the existence of a short bar across the galaxy's center, ending in two short arms that curve in the opposite direction to the outer spiral arms. At the tips of these arms are areas of star formation, part of ring of star formation about 1500 light-years from the galaxy's core that shows up on images taken at ultraviolet wavelengths. This finding is consistent with photographs which show that the color of the galaxy's core is similar to that of the spiral arms,suggesting recent star formation in the region which may be another consequence of the interaction with the nearby dwarf. M100 has figured prominently in attempts to measure the distance scale of the universe, on account of its eminence in the Virgo cluster. Observations of 20 Cepheid variables in its spiral arms with the Hubble Space Telescope led to an accurate determination of its distance (and hence that of the Virgo Cluster) at 56 ± 6 million light-years, announced in 1994.

M101

M101 is a grand spiral galaxy in Ursa Major, located 5.5 degrees north of Eta Ursae Majoris, the star at the end of the handle of the Plough (or Big Dipper). It was discovered in March 1781 by Mechain and added by Messier to his list at the last minute without having checked it. M101 is classified as of type Sc, meaning that its arms are loosely wound, and they show beautifully on long-exposure photographs. Surprisingly, the galaxy can be detected as a pale, rounded disk with binoculars but no details will be visible without a telescope. The brightest clouds of hydrogen in the spiral arms have their own NGC numbers, notably NGC 5461 and 5462 in the longest arm on the galaxy's western side. Three supernovae have been detected, in 1909, 1951 and 1970. M101 is surrounded by a family of about eight small satellite galaxies. Ultraviolet observations in 1981 showed ripples of star formation extending eastwards from M101 towards one of these satellites, the irregular dwarf galaxy NGC 5477, another example of interactions affecting a galaxy's size and structure. From observation of Cepheid variables, M101 is around 25 million light-years away.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

M102

M102 is a duplicate observation of M101, an error due to Mechain. He originally reported it in 1781 to Messier who included it on trust in his third and final list without checking, as he also did with M101 and M103. However, Mechain admitted his mistake in a letter to Bernoulli two years later, and so M102 is now regarded as non-existent.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

M103

M103 is an open cluster in Cassiopeia, about 1 degree northeast of Delta Cassiopeiae, discovered by Mechain in 1781. As with M101 and M102 Messier did not check it before inclusion; had he done so, it seems likely that he would also have spotted the larger and far more comet-like open cluster NGC 663 1.5 degrees to the northeast. Both these clusters are members of the Cassiopeia OB8 association. Admiral Smyth described M103 as a fan-shaped group, and estimated it to have about 20 members easily detectable in his telescope, the four brightest ranging from seventh to ninth magnitude. The brightest of these, which is actually a neat double divisible in small apertures, is now known to lie in the foreground and hence is not a true member at all. According to modern measurements, the cluster lies just over 8000 light-years away and has an age of around 30 million years. M103 was the last object in Messier's third and final list of objects; the subsequent objects were added later by others.

M104

M104 is a spiral galaxy on the border of Virgo and Corvus, popularly termed the SOMBRERO GALAXY because of its resemblance to a wide-brimmed Mexican hat. M104 is a spiral galaxy of type Sa (or possibly intermediate between Sa and Sb), seen only about 6 degrees from edge-on. It was discovered by Mechain, and added by hand to Messier's own copy of the printed version of his catalog. In 1921 the French astronomer C Flammarion suggested adding it officially to the Messier list as M104, and the suggestion has been generally accepted. Photographs show a large central bulge surrounded by a swarm of globular clusters and crossed by a dark lane of dust in the plane of the galaxy; this dark lane seems to have been first detected by William Herschel. Although lying in Virgo, the Sombrero is probably not a member of the Virgo Cluster but is somewhat closer to us, about 35 million light-years away.

M105

M105 is an elliptical galaxy in Leo about 1 degree to the north of M95 and M96 with which it forms a triangle; it is also physically associated with that pair, all three being part of a sparse cluster known as the Leo group of galaxies. It was discovered in 1781 by Mechain and was mentioned in his letter to J Bernoulli in which he admitted the duplication of M101 and M102. Although Messier apparently never saw this object for himself, in 1947 it was identified as NGC 3379 by Helen Sawyer Hogg who proposed its adoption as M105. It is classified as type E1, meaning it is almost perfectly round. M105 has two smaller and fainter companions: NGC 3384, an elliptical, and NGC 3389, a spiral. Radio observations at 21 cm wavelength published in 1989 showed the existence of a ring of hydrogen gas over 600 000 light-years wide orbiting M105 and NGC 3384. There are no signs of any stars or even dust in this ring, suggesting that it is composed entirely of primordial hydrogen left over from the Big Bang that never became part of any galaxy. In addition, nearby M96 seems to be interacting with the ring and capturing some of the gas.

M106

M106 is a spiral galaxy in Canes Venatici just over a degree and a half south of the fifth-magnitude star 3 Canum Venaticorum. At eighth magnitude it is fairly easily within reach of small telescopes. Mechain discovered it in 1781 and mentioned it in the same letter to Bernoulli as his discovery of the objects now known as M105 and M107. In 1947 it was identified as NGC 4258 by Helen Sawyer Hogg, who proposed its adoption as M106. It is classed as type Sb but shows signs of distortion in its spiral arms. Since it is tilted steeply to our line of sight, the full extent of the disturbance is difficult to judge. From radio observations of the velocities of water masers orbiting the galaxy's nucleus, astronomers have deduced the existence of a central body less than a light year across with a mass of around 36 million Suns—in other words, a probable massive black hole. One supernova, 1981K, has so far been seen to erupt in M106. Estimates of the galaxy's distance range from about 23 to nearly 30 million light-years, depending on the technique used.

M107

M107 is a globular cluster in Ophiuchus, about 2.75 degrees south of Zeta Ophiuchi. Like M105 and M106 it was discovered by Mechain but was apparently never seen by Messier. In 1947 Helen Sawyer Hogg identified it as being NGC 6171 and suggested it as an addition to the Messier catalog with the designation M107. Visually it appears relatively sparse by comparison with other globulars, covering about one-third the apparent diameter of the full Moon but appearing only of eighth magnitude. Its distance is around 19 000 light years.

M108

M108 is a spiral galaxy in Ursa Major, located one-third of the way from M97 (the Owl Nebula) to Beta Ursae Majoris. Messier referred to it in his catalog in a note on M97, saying that it lay nearby, but since its position had not been determined he never included it as a separate entry. Like so many objects, it seems to have been first pointed out to him by Mechain. In 1960 the American historian O Gingerich identified this object as NGC 3556 and proposed calling it M108. It is usually classified as type Sc but G de Vaucouleurs regarded it as a barred spiral. In fact its true shape is difficult to ascertain since it is seen nearly edge-on and has a patchy appearance caused by dark clouds of dust. Radio observations, made with the Very Large Array and announced in 1997, have revealed the existence of an invisible shell of hydrogen gas 21 000 light-years across extending from the eastern side of the galaxy. The origin of this shell remains a puzzle; one possibility is that it is the shock wave from the eruption of a huge cluster of supernovae millions of years ago. In recent times it has been the site of only one observed supernova, 1969B.

M109

M109 is a barred spiral galaxy in Ursa Major, lying 0.66 degrees east of Gamma Ursae Majoris in the bowl of the Plough (or Big Dipper). As with M108, it was mentioned by Messier in his note on M97 but was not identified with a known galaxy until 1960, when O Gingerich concluded that it was the same as NGC 3992. M109 is classified as midway in type between SBb and SBc. Much of its central region shows an emission-line spectrum due to ionized gas, evidence of unusual activity in its nucleus and placing it among the type of galaxies known as 'liners'. M109 has been the site of one observed supernova, 1956A.

M11

M11 is an open or galactic cluster in Scutum (2 degrees west and a bit south of η Scuti). It has a very interesting arrow-shaped outline in its densest part and a V-shaped group of stars ahead of the arrow. This prompted Admiral Smyth to describe it as a 'flight of wild ducks' and it is therefore sometimes known as the 'wild duck' cluster. The German astronomer Gottfried Kirch first discovered the cluster in 1681.

M11 contains 2900 stars within a diameter of about 15 light-years. For an open cluster it is very rich and compact, with stars in the central regions separated on average by just 1 light-year. Five hundred of these stars are brighter than 14 mag and the overall brightness of the cluster is 6.3 mag. The distance to the Sun is about 6000 light-years, i.e. it is probably not a condensation in the Scutum star cloud against which it appears but closer to us. The cluster is sometimes thought to be comparatively young at 250 million years but some sources also quote double that value. Support for a higher age comes from the relative abundance of yellow and red giants of absolute magnitude of -1 (i.e. comparatively faint old stars). In fact, M11 has more yellow giants than most open clusters and is similar to M67 in that respect.

M110

M110 is the second of two small elliptical galaxies near the Andromeda Galaxy, both of which can be seen through small telescopes. Messier cataloged the first companion of M31 as M32, but strangely never included the second on his list, even though he showed M31 with both companions in a drawing in 1807 and claimed to have discovered it in 1773. Until 1966 it was known solely as NGC 205, when the English amateur astronomer K Glyn Jones proposed adding it as M110, the final Messier object. M110 lies over 1 degree northwest of M31 and although it is larger than M32 it is more difficult to see, having a lower surface brightness. It is classified as type E5 or E6, meaning that it is considerably elongated in shape. Two unusual aspects of M110 are the existence of dust clouds and clusters of young stars near its center, not normally encountered in elliptical galaxies.

M12

M12 is a globular cluster in Ophiuchus close to M10 but slightly larger, fainter and much less concentrated towards the center. It was discovered by Charles Messier, but William Herschel was the first to resolve it into stars in 1783.

The cluster has a diameter of about 100 light-years and is at a distance of about 19 000 light-years from the Sun. It is a very loose cluster and was at one point even thought to be an intermediate type between globular and galactic cluster (this was before it was discovered that the two types of cluster are completely different in age and stellar population). It has a visual brightness of 6.7 mag and a diameter of 100 light-years. Allan Sandage investigated the cluster for variables and found only 13.

M13

M13 is a globular cluster in Hercules (2.5 degrees south of η Herculis), the 'Great Hercules Globular Cluster' discovered by Edmund Halley in 1714 who noted that 'it shows itself to the naked eye when the sky is serene and the Moon absent'. It was first resolved by William Herschel and has since been the target of much professional and amateur interest, mainly because it is very bright and easily observable from the northern hemisphere.

M13 is a fairly open cluster, almost perfectly circular in outline, with a diameter of 150 light-years, a visual brightness of 5.8 mag and over half a million stars. At its center the stars are 500 times more concentrated than they are in the solar neighborhood. Its age was estimated by Arp to be 14 billion years (1962). The high latitude of the cluster leads to a large major axis of its orbit which means that it spent most of its long life at a great distance from the disruptive tidal effects of the Galactic Center—hence the great concentration of stars and its almost perfect shape. Its distance to the Sun is 22 800 light-years as measured from its variables (slightly higher from radial velocity measurements). Like M3 it contains one hot, young, blue star (Barnard no 29) whose presence in this old cluster cannot easily be explained. It also contains 15 variable stars and four apparently star-poor regions.

M14

M14 is a galactic cluster in Ophiuchus, discovered by Messier and first resolved into component stars by William Herschel in 1783. It has a diameter of 55 light-years and lacks a dense central concentration. The outline is slightly flattened (ellipticity type E1) and its visual brightness is 7.6 mag. The distance to the Sun is approximately 27 400 light-years.

M14 is relatively rich in variable stars, 70 having been discovered so far. Of particular interest is a nova (16 mag) that appeared in this cluster between 21 and 28 June 1938 but was not discovered until 1964 when Amelia Wehlau of the University of Western Ontario found it during a search of photographic plates taken by Helen Sawyer Hogg between 1932 and 1963. It was only the second nova to appear in a globular cluster (the first being in M80 in 1860) and the first ever to be photographed.

M15

M15 is a globular cluster in Pegasus (close to ϵ Pegasi), first discovered by Jean Dominique Maraldi on 7 September 1746. It was resolved into stars by William Herschel.

This is another very rich and old globular cluster. It has a diameter of 88 light-years and its superdense core is undergoing collapse. This often features in the dynamic evolution of globular clusters: of the 147 in the Milky Way, 21 have a collapsed core (such as, e.g., M30 and M70) and there are eight more candidates. In the case of M15 it is not entirely clear whether the core has collapsed simply under its own gravity or whether there is a supermassive object at the center resembling the objects thought to be at the centers of galactic nuclei. The Hubble Space Telescope has therefore recently taken pictures of the dense core. By measuring the velocities of the central stars it will be possible to resolve this question.

The age of the cluster was estimated at 12 billion years. It has a visual brightness of 6.2 mag and is at a distance of around 32 000 light-years.

M15 is the third richest cluster in terms of variables: 112 have been discovered so far, one of which is a classical (type II) Cepheid. It also contains nine pulsars, one of which seems a component of a neutron star binary. Systems of neutron-plus-neutron star binaries are particularly interesting because they exhibit strongly general relativistic effects, such as significant perihelion shifts, effects on passing light and gravitational waves which carry away rotational energy and lead to a slowing-down of the pulsar frequency as well as of the orbital period. It is also the first cluster in which a planetary nebula could be identified, and in 1988 an x-ray source was found to be a normal-plus-neutron star binary system with a period of 9 h.

M16

M16 is an open cluster in the constellation Serpens, associated with the EAGLE NEBULA (1 degree north and 2.5 degrees west of γ Scuti). It was discovered by de Chéseaux in 1746 as a 'cluster of stars' and sits on the next inner spiral arm of the galaxy away from us next to M17.

M16 is in many ways similar to the Lagoon Nebula M8. The cluster formed from the gas of the Eagle Nebula and its bright young stars now light it up. The nebula exhibits ongoing star formation in the dark 'elephant trunks' visible to the north. It also contains the black globules that are collapsing protostellar clouds (mainly to the southeast). The Hubble Space Telescope has taken many detailed pictures of this particularly beautiful object.

The star cluster is one of the intrinsically most luminous with an absolute magnitude of -8.21. It has a diameter of 7 arc min at a distance of 7000 light-years and a visual brightness of 6.4 magnitudes. Its age has been estimated at 5.5 million years.

M17

M17 is a diffuse nebula in Sagittarius variously known as the Omega, Swan, Horseshoe or Lobster Nebula. It was discovered by de Chéseaux in 1746 and is a neighbor to M16.

The diameter of its brightest part is about 15 light-years but the low-luminosity and dark material extends to a size of at least 40 light-years. Like many nebulae, it consists of bright filaments and dark, obscuring matter and star formation has either only recently stopped or is still proceeding in its center. A cluster of about 35 bright but obscured stars is embedded in it and the nebula shines by re-emitting the light absorbed from these stars. The mass of the brightest gas has been estimated to be about 800 solar masses (much more than in the otherwise comparable Orion Nebula, M42). The main difference between this nebula and M8 and M16 is the difference in its absorption regions: M17 contains a large amount of dark, obscuring material, more so than either of the other two nebulae.

Its distance to the Sun is between 5 and 6000 light-years. The nebula is a radio source in 9.4 cm and has been shown to have a 29%-polarized infrared emission. This might indicate the existence of 'bipolar nebulae' or lobes of scattering material in the polar regions. A twin-lobed radio source extending from the central infrared cluster has also been detected.

M18

M18 is an open cluster in Sagittarius discovered by Messier as a 'cluster of small stars'. It lies between M17 and M24.

The cluster contains about 20 members and has an angular diameter of 9 arcmin. Its visual magnitude is 7.5 which makes it one of the looser and poorer clusters. Correspondingly, it has not received much attention from scientists to date. Its distance from the Sun has been estimated at 4900 light-years but that value is disputed with some sources quoting up to 6000 or less than 4000 light-years. M18 is generally considered to be quite young (32 million years). Its hottest stars are of type B3 (i.e. very hot and young) but it contains bright yellow and orange as well as blue stars.

M19

M19 is a globular cluster in Ophiuchus, discovered by Messier but first resolved by William Herschel in 1784. It can easily be located at 8 degrees due east of Antares and embedded in the Milky Way.

It is at a distance of 27 000 light years (4600 light-years from the Galactic Center), has a diameter of 25 light-years and a visual brightness of 6.8 mag. M19 is the most oblate of the known globular clusters with an ellipticity E3–E4.

M2

M2 is a bright globular cluster in Aquarius forming an almost right-angled triangle to the north with α and β Aquarii. It was first mentioned by Jean Dominique Maraldi in 1746 but independently rediscovered by Charles Messier who described it as a nebula without stars. William Herschel was the first to resolve the stars. M2 is a rich and compact globular cluster with 150 000 stars within a diameter of about 150 light-years and with a slight ellipticity (type E1, meaning it is almost perfectly round). Its visual brightness is 6.5 mag and its distance from the Sun is 36 000 light-years (i.e. well beyond the Galactic Center)—but there is some doubt about this number, with some sources setting the distance at around 50 000 light-years. The age of the cluster has been determined at 13 billion years.

Compared with other globular clusters, M2 has a relatively low number of variable stars: so far, 21 variables have been detected, most of which are RR Lyrae stars with periods of less than a day, but there are also three classical (type II) Cepheids with periods between 15 and 19 days and one RV Tauri star with a period of 67 days. The cluster's brightest stars are red and yellow giants of 14.1 mag (absolute magnitude −3.0).

M20

M20 is a diffuse nebula in Sagittarius known as the 'TRIFID NEBULA' because of its three-lobed appearance. It is situated roughly 2 degrees northwest of M8. Messier described a 'cluster of stars', William Herschel assigned different numbers to different parts of the object and John Herschel was the first to use the term 'trifid'.

M20 is a typical emission nebula where young hot stars at the center excite the gas of the surrounding nebula which then de-excites by emitting a reddish glow. It is itself surrounded by a blue reflection nebula particularly conspicuous to the north. The three-part division is due to dark obscuring filaments between the bright nebulae. It has a diameter of 30 light-years and a distance of 2200–7600 light-years from the Sun. Its visual brightness is 9 to 6.8 mag—the range of values deriving from the fact that the overall brightness is hard to detect in this object whose central region is dominated by a few very bright stars. The brightest of these are a triple system consisting of three very hot and four fainter members. Like M8 and M42, M20 is a radio source at 9.4 cm. This relatively short-wavelength radiation indicates that the source must be thermal emission and the temperature of the nebula has been calculated from this to be about 10 000 K.

M21

M21 is a young open cluster in Sagittarius, close to but not associated with the Trifid Nebula (M20). It was discovered in 1764 by Messier who described it as a 'star cluster near M20'.

The cluster has about 100 probable member stars, some of which are early B-type stars and the reddening through interstellar dust is comparatively low. For that reason, M21 lends itself to star formation studies and to the calibration of distance indicators (not having to worry about the reddening is always an advantage for that). However, research interest in this cluster has been quite low and it is one of the few young open clusters still lacking a detailed study. Its age is commonly thought to be about 8 million years and its distance is set at 4300 light-years. There is some controversy associated with this number, however, and it is not entirely clear whether M20 or M21 is closer to us.

M22

M22 is a rich, old globular cluster in Sagittarius, very bright (5.1 mag) and fairly close (about 10 000 light-years) but only 1 degree out of the ecliptic. Its vincinity to the ecliptic plane is both an advantage and a disadvantage: it often appears in conjunction with planets and was discovered in 1665 (the first globular cluster recorded) by the German astronomer Abraham Ihle while he was observing Saturn. But since it is viewed along a line of sight passing through the galactic disk and bulge, the cluster is heavily reddened (i.e. the light from the cluster is shifted into the red end of the spectrum by scattering off dust grains) and so basic parameters like age and metallicity are difficult to determine exactly. In the case of M22, they are still somewhat uncertain, with the age being normally set at about 12 billion years.

Because of its brightness, the cluster has had a rich observational history, appearing in the lists of Halley, Lacaille, le Gentil and de Chéseaux before being included in Messier's catalog. William Herschel was the first to resolve it into its constituent stars and in 1959, M22 was one of the very first clusters for which a color–magnitude diagram was obtained. More recently, it has been investigated for variable and other exotic types of star: 32 variables and one planetary nebula have been found so far and since 1992 three possible CH stars (a very exotic type of binary, rare in clusters, see also M14) have been identified. The cluster is potentially very interesting because it is indicative of conditions in the very early protogalaxy, but because of the problems mentioned above (mainly the reddening) it has not yet been extensively studied.

M23

M23 is a very poor, loose open cluster in Sagittarius (one of Messier's original discoveries) with boundaries that are difficult to define. So far, 150 stars within a linear diameter of about 15 light-years have been shown to be members. The cluster is old for an open cluster (about 300 million years) and is thought to have spent a large fraction of its lifetime in the gas-poor regions between the spiral arms of our Galaxy. It can therefore be used to test theories about the effect of gas-rich and gas-poor environments on stellar evolution and a recent study on M23 indicates that the environment does not greatly influence the metallicity of stars after they have formed.

M24

M24 was discovered by Messier in 1764 as a 'star cluster'. It is not, however, a real cluster but simply a patch of the Milky Way that is seen through a tunnel in the otherwise obscuring interstellar dust and therefore looks like a cluster. This patch is visible to the naked eye two-thirds of the way between γ Scuti and μ Sagittarii. It has an average magnitude of 4.6.

A dim open cluster can be detected inside the star cloud (NGC 6603) which in some cases is identified with the Messier object. This is wrong, however, since Messier clearly described the cloud rather than the dim (11 mag) cluster.

The interstellar medium has a tendency to accumulate in huge clouds about 25 light-years across. Small windows in these clouds are important for our understanding of galactic structure since they allow us to study material that would normally be obscured.

M25

M25 is an intermediate-age (90 million years) open cluster in Sagittarius that was discovered by de Chéseaux in 1746. It has a visual magnitude of 6.5 and is conspicuous even with normal binoculars. Because of its relatively small distance (about 2000 light-years) and the comparative ease with which it can be observed, it was one of the first used for studies of variable stars. In 1960, Allan Sandage identified its one Cepheid variable, U Sagittarii, and used it to calibrate the period–magnitude relationships for Cepheids. Since then, however, clusters richer in variables have been identified and interest in M25 has waned.

M26

M26 is an open cluster in the constellation Scutum, an apparent neighbor to M11. It was possibly seen by Le Gentil before 1750, but Messier discovered it independently in 1764 and noted that it was 'not distinguished in 3.5 foot telescope'.

Of the 90 confirmed members of this cluster, 25 are very bright but no extensive studies into the stellar population or the range of masses have been conducted so far. In fact, M26 is one of the least observed objects in the Messier catalog with its latest research paper published in 1940 (when its age was determined to be about 90 million years and its distance 5000 light-years). Its most distinguishing feature is an apparent ring of low stellar density around the center. In a region of diameter 3 arcmin (cluster diameter 15 arcmin) the density of stars is about 13% less than in the adjacent areas. This is now thought to be caused by dust extinction.

M27

M27 is a planetary nebula in Vulpecula also known as the 'DUMBBELL NEBULA' because of its shape. It was the first planetary nebula to be discovered (Messier, 12 July 1764), and even though it is neither the largest nor the brightest, it is the easiest to observe: larger planetary nebulae tend to be fainter and brighter ones tend to be small.

The nebula was created about 3000 to 4000 years ago when a giant star blew off its outer layers. It is therefore still expanding at a rate of 6.8 arc seconds per year and the central star (the remaining core of the giant) is a hot, blue subdwarf dwarf with a temperature of 85 000 K (spectral type O7) with possibly a faint yellow companion. This star emits light mostly in the non-visible parts of the spectrum, which is then absorbed and re-emitted by the nebula in the visible (predominantly in one green spectral line). The distance to the planetary nebula is difficult to determine (a common problem for these objects): values proposed range from 400 to 3500 light-years. But if the distance is taken to be 1200 light-years then the central star has an intrinsic luminosity of one-third of the solar luminosity and the nebula as a whole emits 100 solar luminosities entirely in the visible part of the spectrum. This gives it an apparent magnitude of 7.4 (i.e. it is not visible to the naked eye). The angular diameter of the nebula's brightest part is 6 arcmin and the dumbbell shape is due to us observing the nebula from its equatorial plane. If we saw it from one of the poles, it would look ring-shaped, more like M57.

M28

M28 is a rich, dense globular cluster in Sagittarius. It was discovered by Messier as a 'nebula containing no star' and first resolved into its component stars by William Herschel.

As for most of the dense globular clusters, M28 is interesting mainly because of its variable stars and because of its binary star systems. The evolution of binaries in rich environments has received a lot of attention recently, as they seem less common in these clusters than they are predicted to be. On the other hand, the more exotic varieties of binary systems (such as neutron star binaries) seem particularly frequent in the cores of rich clusters.

In 1987 a millisecond pulsar was discovered in M28 (the second to be found in a globular cluster after the discovery of the pulsar in M4). It rotates over 2000 times faster than the Crab pulsar (once every 11 milliseconds). Periods as short as this are thought to be produced by interaction with a binary companion, and in 1997 an x-ray burst in M28 was interpreted to be evidence for the neutron star slowly accreting material from that companion. Interest in M28 since then has mainly centered on its x-ray activity.

M29

M29 is a very young, open cluster in Cygnus. It was discovered by Messier in 1764 and is particularly highly obscured by interstellar material. It has been estimated that in the line of sight to M29, the interstellar dust is 1000 times more dense than usual. Scattering of the cluster light leads to an overall reddening and dimming together with a high polarization. These effects make it difficult to gauge how much light and which color is really emitted by the member stars, and hence their age and distance is difficult to determine.

Within correspondingly large error bars, M29 is thought to be young (i.e. below 10 million years) and only about 4000 light-years away. It contains one variable of γ Cas type and several more suspected variables, and some investigation into its three binary systems and the hot stars in the cluster have been done, but these studies are all rendered difficult by the uncertainties associated with the fundamental parameters.

M3

M3 is a very rich globular cluster in the constellation Canes Venatici. It was the first original discovery by Messier and probably the object that sparked his systematic search for nebulae and clusters. It has approximately 500 000 member stars within a diameter of 300 light-years and is with a visual brightness of 6.5 mag one of the brightest clusters in the northern hemisphere. Its distance to the Sun is about 30 600 light-years and its age has been estimated at 6.5 billion years.

M3 is a very well-studied globular cluster partly because it contains more variable stars than any other. So far, 212 have been counted and 186 periods determined. The brighter stars are of remarkably uniform magnitude and there is one very hot, young, blue star (discovered by Allan Sandage) whose presence in this old cluster continues to be a mystery (see also M13). Current theories propose that the young star might have been captured relatively recently by the gravitational attraction of the cluster as a whole.

M30

M30, like M15, M70 and possibly M62, is an old globular cluster (in Capricornus) whose central core has undergone gravitational collapse. It was discovered by Messier in 1764 but has only been very actively studied since about 1994 when it was discovered that the luminosity function of the cluster does not agree with the function shape derived from standard stellar evolution models. M30 has therefore become a test case for the study of the modification of stellar populations in dense collapsed regions.

Overall the light emitted by the cluster is much more blue than would be expected for an object this age. It has a higher frequency of blue stragglers (blue, hot main sequence stars which seem too young to be in such an old cluster) in the core than other globular clusters (48 have been identified so far), which supports the theory that they are formed by star or binary mergers. Additionally, the core is thought to be unusually poor in red giants, but so far no theory has been able to successfully explain this.

M31: The Old Stellar Populations

M31 (the Andromeda nebula) is a large highly inclined spiral galaxy about 1.4 times as luminous as our Galaxy. The Milky Way and M31 are the two dominant members of the Local Group of galaxies. The proximity of M31 (about 770 kpc from the Sun) allows its stellar populations to be studied in some detail with the Hubble Space Telescope and large ground-based telescopes. M31 contains all the usual ingredients of a spiral of intermediate (Sb) Hubble type: atomic, molecular and ionized gas, dust, dark matter and stars of all ages. For the study of stellar populations, however, M31's oldest stars are of particular interest, because they show some very significant differences, as a population, from the oldest stars of our Galaxy. Although we do not yet fully understand the reasons for these differences, they surely came about through differences in the processes by which these two large galaxies formed in the early universe.

The bulges of M31 and the Milky Way

In the Milky Way, the disk stars are all younger than about 10 Gyr. The oldest stars (ages up to about 14 Gyr) are found in the spheroidal components of the Galaxy, i.e. the bulge and the very diffuse stellar halo which extends out to at least 100 kpc from the galactic center. These old non-disk components, the bulge and the stellar halo, are often discussed together, although their origin may be quite different.

The structure of the spheroidal component was established by dynamical processes, like the merging of clumps of gas and dark matter and the dynamical instabilities of flat disks, which began at the same time as the oldest stars were forming. So its structure and its old stellar population are intimately related. It is interesting therefore to contrast the structure of the spheroidal components of M31 and the Galaxy before we go on to discuss their stellar content.

The bulge of M31 is relatively large, about 25% of the mass of the disk, while for our Galaxy the corresponding fraction is about 15%. Although these fractions are not so different, the bulges of M31 and our Galaxy are structurally different and typical of large and small bulges respectively. The M31 bulge has the spheroidal shape and the characteristic radial dependence of surface brightness that is seen in most large bulges. Its surface brightness $I(r)$ follows the empirical de Vaucouleurs law $\log I(r) \propto -r^{1/4}$, from a radius of 200 pc out to beyond 20 kpc. From dynamical theory, this $r^{1/4}$ law is associated with the violent relaxation process, in which rapid changes of the gravitational field statistically redistribute the orbital energies and angular momenta of the stars. The stellar system that emerges from this redistribution has the characteristic $r^{1/4}$ surface brightness distribution. Such rapid changes of the gravitational field come about, for example, as clumps of matter interact and merge to form the early bulge. The compression of gas in these same mergers is believed to set off the first bursts of star formation that produced the stars which we now see as the old stellar population of M31.

The bulge of the Milky Way is very different. Its smaller bulge is seen edge-on and shows a box-like shape, with a surface brightness distribution that is exponential with radius. This kind of structure is common for small edge-on bulges. From studying the motions of gas in our Galaxy and in other galaxies with bulges that appear boxy when seen edge-on, we know that these bulges would not appear round and symmetric when viewed from above. The boxy shape is dynamically associated with an asymmetric bar-like structure. These small bar-bulges are believed to form from the disks of the parent galaxies, through the instability of the rotating disk. This is likely to be a much more quiescent process than the violent merging that led to the formation of the larger $r^{1/4}$ bulges.

In comparing the bulges of M31 and the Galaxy, it seems likely that the different dynamical histories of these two bulges would lead to different star formation histories. We might expect the violent early merger processes in M31 to be associated with rapid star formation and chemical evolution, with chemically enriched stars flung out to large distances by the violent dynamical relaxation. On the other hand, in the inner regions of our Galaxy, the star formation and bulge formation appear to have occurred in a more sedate disk-like environment; the bulge itself formed out of the disk, and the stars of the bulge would remain confined to the inner regions of the Galaxy.

The differences between the old stellar populations of M31 and the Galaxy are most readily studied by observing individual stars in globular clusters and in the outer regions of the diffuse stellar populations in these two galaxies.

The halos of M31 and the Galaxy

First we compare the stellar populations of the globular star clusters in M31 and the Galaxy which have now been studied in great detail. Their stellar color–magnitude diagrams (CMDs) and integrated spectra give estimates of chemical abundances and ages. In most of their properties, the clusters in the two galaxies are alike. The stellar populations within individual clusters of the same chemical abundance are similar, as are the distributions of luminosity of the clusters in the two cluster systems and the radial distributions of the clusters within their parent galaxy. The M31 and Galactic globular clusters cover a similar range of chemical abundance, with the outer clusters of M31 being marginally more metal-rich than their Galactic counterparts[1].

Despite the similarities in the properties of the globular clusters of M31 and the Galaxy, the metallicity distributions in the diffuse (i.e. non-cluster) stellar halos

[1] Here 'metal' means all elements heavier than He, and is often denoted generically as Fe: metal abundance is usually expressed in terms of the (Fe/H) ratio as $[\mathrm{Fe/H}] = \log_{10}$ (stellar Fe/H)/(solar Fe/H). For example, a low metal abundance of $[\mathrm{Fe/H}] = -2$ corresponds to 0.01 of the solar value.

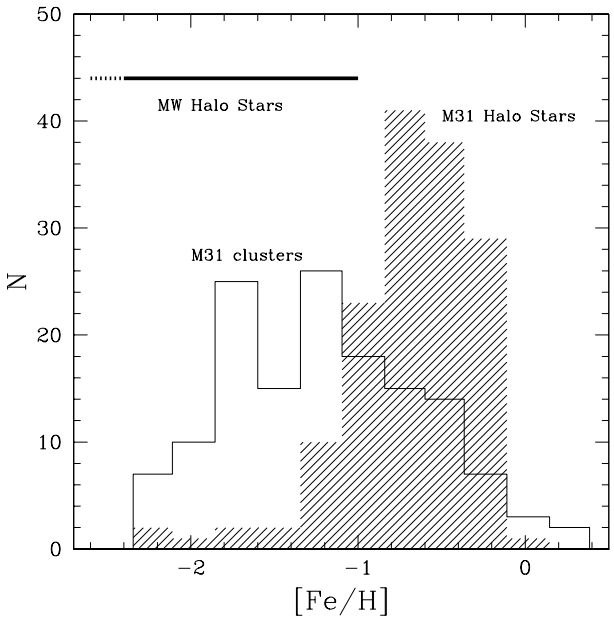

Figure 1. Comparison of metallicity distributions of the M31 halo field stars (hatched) and the M31 globular clusters (adapted from Durrell *et al* (1994)). The bar at the top left indicates the metallicity range of the halo field stars in the Galaxy. The M31 halo stars are much more metal-rich than the Galactic halo stars, although the metallicity distributions for the globular clusters in M31 and in the Galaxy are similar.

of the Galaxy and M31 are strikingly different. For our Galaxy, most halo stars have metallicities [Fe/H] < -1, with a mean of about -1.6. For the outer bulge or halo of M31, CMDs are now available for many fields at distances between about 7 and 40 kpc from the center. All of these studies show that the M31 halo stars cover a very wide range of metallicities, from near-solar down to metallicities [Fe/H] < -2, but the mean metallicity is about -0.6, much higher than for the halo of the Galaxy. This holds true even at the largest radius in M31. Figure 1 shows the marked difference between the metallicity distributions of the stellar halo and the globular clusters of M31. For comparison, the range of metallicities for the Milky Way halo stars is also shown.

Conclusion

What are we to make of the similarities and differences in the stellar populations illustrated in figure 1? The globular clusters in M31 and the Galaxy have similar distributions of metallicity, while the outer stellar halo of M31 is much more metal rich than its Galactic counterpart. These are all old stellar populations, so the origin of the differences will be found in the details of how these galaxies formed, and this is still poorly understood.

Some useful clues are emerging about the nature of the globular clusters. The violent environment of present-day merging galaxies is seen to produce large numbers of young globular-like star clusters. This suggests that the old clusters of our Galaxy and M31 formed in the very early phase of galaxy formation, as clumps of matter were merging together to build the galaxy and the chemical enrichment was proceeding rapidly through massive star formation triggered by the merging.

When we compare the diffuse halos of M31 and the Galaxy, the similarity ends. The two halos are chemically very different, and we must conclude that they formed along quite different paths. At this time, it seems likely that in M31's outer regions we are seeing chemically enriched stars that were scattered out to large radii as part of the violent formation of its $r^{1/4}$ bulge. On the other hand, the halo and bulge of our Galaxy appear to be chemically and dynamically distinct. The Galactic bulge rotates and is relatively metal-rich, like the M31 halo stars in figure 1, while the halo shows no significant rotation and is metal-poor. Following the seminal work of Searle and Zinn (1978), it is now widely believed that the metal-poor stellar halo of our Galaxy is just the debris of small metal-poor satellite galaxies that were accreted and tidally disrupted by our Galaxy. The tidally disrupting Sagittarius dwarf galaxy shows that this process of accretion and halo-building is still going on in our Galaxy.

For more background on M31, see the articles on the ANDROMEDA GALAXY and on the LOCAL GROUP in this encyclopedia.

M32

M32 is an elliptical galaxy (type E2) in Andromeda, a dwarf companion to the Andromeda galaxy M31. It was the first elliptical galaxy to be discovered (Le Gentil, 1749). Its proximity (725 kpc) allowed its outer regions to be resolved into stars by the first generation of large optical telescopes (Baade 1944). Dynamically, it is thought to be dominated by a central supermassive object (similar to the nucleus of M31).

M32 is in many ways a very unusual object. Compared with other dwarf galaxies of the same absolute brightness, its central surface brightness is four orders of magnitude higher and its core radius three orders of magnitude smaller. It is therefore sometimes referred to as a 'compact' elliptical to distinguish it from 'dwarf' ellipticals. Only a very few similar objects have been found, and none is as extreme. Additionally, its nucleus seems to be several billion years younger and more metal-rich than the outer regions: excess radiation in the ultraviolet indicates a hot, young stellar component in the core (figure 1). This is unexpected since elliptical galaxies are generally thought to be older than spirals and to have finished star formation long ago.

These peculiarities, coupled to the fact that M32 and M110 are the closest elliptical galaxies and therefore our best chance to study such objects, have led to M32 being the target for a variety of studies. So far, no single theory has been advanced that could explain all of the galaxy's puzzling characteristics.

M33

M33 is a spiral galaxy in Triangulum, an apparent neighbor to and possibly distant companion of M31. It is of type Scd, i.e. a late (advanced in its evolution) spiral without a bar or a central black hole, and small compared with the Milky Way and M31 (as all galaxies in the Local Group are small compared with these). The Milky Way and M31 are giant spirals whereas M33 is closer to what is thought to be the average size for a spiral galaxy.

It was discovered by Hodierna before 1654 and independently rediscovered by Messier in 1764. M32 is visible to the naked eye under exceptionally good conditions just south of the line joining α Trianguli to β Andromedae.

The distance to this galaxy is 3 million light-years. It has a diameter of about 50 000 light-years (half of that of the Milky Way) although faint outliers are supposed to extend out much further (more than 60 000 light-years). Its mass is between 10 and 14 billion solar masses (luminous matter only—the size of the dark matter halo of all close galaxies is still a matter of much research and controversy).

The most striking feature of M33 are the pronounced spiral arms which include globular clusters and population II stars as well as large regions of ionized hydrogen (H II). In particular there is one H II region which is roughly 1500 light-years in diameter and so clearly visible as a knot in the spiral arm that it has its own number in Herschel's catalog. It is the largest known H II region, has a spectrum similar to the Orion nebula (M42) and contains over 200 hot, massive, young stars. In addition, there are over 80 diffuse emission nebulae in the spiral arms (visible as knots) and some ongoing star formation in the main disk. M33 is therefore a good target for the study of star formation in an entire galaxy.

The globular clusters in its halo are quite different from the Milky Way globular clusters and seem to be several billion years younger. So far, there is no satisfactory explanation for this phenomenon. Its overall stellar population, on the other hand, does not show any obvious irregularities. No supernovae have yet been observed but several supernova remnants. One hundred and twelve variables have been identified: amongst them four novae, 25 Cepheids and one eclipsing x-ray pulsar (i.e. a neutron star with some binary companion of possibly quite considerable mass). The rest of the variables are mostly RR Lyrae stars.

M34

M34 is an open cluster in Perseus just north of the straight line between Algol (β Persei) to γ Andromedae. Because of its great angular diameter (35 arcmin, larger than the full Moon) and its relatively high apparent magnitude (5.5) it is easily visible to the naked eye. It was first discovered by Hodierna before 1654 and later independently rediscovered by Messier.

The cluster is fairly loose with only about 100 stars inside the diameter (translating to 14 light-years at a distance of 14 000 light-years). Its age has been estimated at about 250 million years, which puts M34 just between the Pleiades (70 million years) and the Hyades (800 million years)—two of the best studied open clusters in the sky. It can therefore be used for comparison studies of the evolution of chromospheric activity, rotational velocity and lithium abundance in solar-type stars which are common in all three clusters.

M35

M35 is a rich open cluster in Gemini (in the direction of the galactic anticenter). It is of roughly intermediate (but not very well determined) age and is visible to the naked eye under good conditions (5.3 mag).

M35 was probably first discovered by de Chéseaux in 1746: he mentioned a 'star cluster above the northern feet of Gemini'. More recently, because of its high luminosity, the large angular diameter (28 arcmin) and its small distance (about 800 pc), it has been one of the most frequently photographed objects in the catalog. Pictures of this cluster taken over the last 100 years can be used for extensive study of the cluster members' proper motions and hence a lot of recent research has centered on the comparison of its internal motion to the predictions for the dynamical evolution of open clusters.

M36

M36 is an open cluster in Auriga and the first of a set of three (true neighbors) in the southern part of that constellation (the other two are M37 and M38). All of these were first discovered by Hodierna before 1654.

Amongst the roughly 60 members of M36 are many rapidly rotating stars very similar to the stars found in the Pleiades cluster M45. The cluster does not contain any red giants (unlike its neighbors M37 and M38) and is therefore thought to be very young, i.e. only about 25 million years.

M37

M37 is the brightest of the open clusters forming the group of three in Auriga (see also M36, M38). It has a visible magnitude of 6.2, is therefore not visible to the naked eye. Its diameter is about 20–25 light-years and with over 500 members it is one of the richer open clusters. It contains at least 12 red giants and is estimated to be about 300 million years old, i.e. it is a pretty evolved type of open cluster. There is some suggestion from radial velocity measurements of the member stars, that it is contracting slowly.

M38

M38 is the faintest of the three open clusters in Auriga. It forms a distinctive π- or cross-shape and contains approximately 150 stars. Of these, only one is a yellow giant and the age of the cluster has been estimated at about 220 million years. Because of this age and its proper motion it has been suggested that this cluster is in a binary association with the open cluster NGC 1907 but this has yet to be conclusively proven.

M39

M39 is a sparse open cluster in Cygnus, and even though Messier independently discovered it in 1764, its visual magnitude of 5.2 and extended size (32 arcmin, larger than the full Moon) makes it likely that it had been observed previously. There are claims that Le Gentil identified it in 1750 but they are doubtful, since he did not leave a good position, and there are suggestions that Aristotle described the cluster as early as 325 BC.

M39 is thought to have about 81 member stars, but they are difficult to identify since the same area is very rich in faint Milky Way stars. These members are all main sequence with no stars that have spectral type earlier (i.e. hotter) than A, and the cluster has been dated to about 230 to 300 million years. Its small distance (about 300 pc) and large size make it an easy object to study, and recent interest has concentrated on the cluster's dynamical evolution and on comparing its stellar population to other clusters of the same age and metallicity.

M4

M4 is a very loose globular cluster in Scorpius and the nearest globular cluster to the Sun. It was discovered around 1745 by Philippe de Chéseaux but remained unpublished (de Chéseaux included a list of nebulous objects in a letter to a friend; eight of these objects were original discoveries but he never published them and so they were not generally known to his contemporaries). It is a very open (or loose) cluster with a distinct bar-like structure, about 10 300 member stars, and a diameter of about 55 light-years. At its distance of 7000 light-years that means that the angular diameter is close to that of the full Moon. It is not as conspicuous as could be expected from this, however, since it is heavily obscured by dust (the ρ Ophiuchi dust complex is nearby). Nevertheless, it can be detected with the naked eye about 1.3 degrees west of Antares.

M4 includes 43 variable stars and in 1987 the first millisecond pulsar was discovered amongst its members. It has a period of 3 ms and is therefore 10 times faster than the Crab pulsar (see M1)—periods as short as this are now thought to be produced by some interaction with a binary companion. The Hubble Space Telescope has taken pictures of some of the 40 000 white dwarves that the cluster is predicted to contain. Analysis of these pictures will allow important conclusions to be drawn about the cooling rate of white dwarves which is crucial for the determination of the Galaxy's age from white dwarf temperatures.

M40

M40 is a fluke in Messier's list of nebulous objects since it is a double star in Ursa Major, also known as Winnecke 4. Messier noted its position when he was looking for a nebula reported by Hevelius in the same region (probably because he thought Hevelius might have mistaken this double star for a nebula). Hevelius had described a 'supra tergum nebulosa', a nebula above the back (of Ursa Major), but this is likely to be a mistake, since none has ever been found in the region, and even the double star is some way from the position described.

The double star has two components, a primary of spectral type G0 (same type as the Sun but four times brighter) and a secondary of spectral type F8 (slightly hotter). Its distance has been recently determined by the Hipparcos satellite to be 510 light-years. Many published versions of Messier's catalog leave out this object since it does not fit with the rest of the list.

M41

M41 is a poor, nearby open cluster in Canis Maior. It is, with a visible magnitude of 4.6, comparatively bright, and there have been suggestions that it was first recorded by Aristotle in 325 BC. If this were true, M41 would be the faintest object recorded in antiquity. However, the reference is not entirely clear. It is clear that the cluster was both included in Hodierna's list of nebulous objects (16654) and recorded by Flamsteed in 1702.

For a poor open cluster, M41 has a remarkably rich population of unusual stars. The percentage of binary systems is thought to be as high as 40% from spectroscopic evidence. Additionally, there are several luminous red giants, some of which are suspected of low-level variability, and two confirmed white dwarfs. Research has very much concentrated on these exotic stars but studies of the cluster are still hampered by the fact that its basic parameters (age and distance) have not so far been satisfactorily determined. The literature quotes age determinations between 30 and 200 million years with the uncertainty due to the fact that the exact amount of reddening for this cluster has been difficult to pin down. Starlight will be scattered off the interstellar dust and thus be shifted into the red part of the spectrum, making the emitting stars look both older and fainter than they really are. To correct for this effect, it is important to have some idea of the amount of interstellar dust in the line of sight and this is not always easy to determine.

M42

M42 is better known as the ORION NEBULA. It is a huge (four times the area of the full Moon), bright (4 mag) diffuse nebula which constitutes the main part of a still larger cloud extending well over half the constellation of Orion. This cloud also contains M43, Barnard's Loop, the Horsehead Nebula and the reflection nebula around M87.

As a whole, the nebula is similar to other diffuse nebulae but it is the brightest and the star formation region closest to Earth. It harbors at its center one of the youngest known clusters, the Trapezium cluster. Its stars light up the nebula (consisting of pure ionized hydrogen in the central regions and some gas and dust in the outer parts) with the starlight partly reflected and partly absorbed and re-emitted. Because of its great luminosity, rich structure can be discerned in the nebula even with conventional telescopes, and detailed investigation with the Hubble Space Telescope has recently uncovered such details as disks of dust and gas forming around and interacting with the bright stars. These are thought to be the beginnings of planetary systems.

At its northern end, the nebula is divided into two parts by a prominent dust lane. Messier assigned an extra number (M43) to the smaller part.

As would be expected for such a bright object, M42 has a rich history in recorded astronomy from Ptolemy (who cataloged the Trapezium cluster if not the nebula itself) via the French lawyer and amateur astronomer Nicholas-Claude Fabri de Peiresc (1610), Christian Huygens (1684), Hodierna (before 1654, he produced the first drawing) and Charles Messier.

Considering that Messier's list concentrated mainly on faint, nebulous, not well known or even unknown objects, it is surprising that he chose to include the objects M42 to M45 which are all bright and were well known at his time. He recorded them in a single night (4 March 1769) and it has been suggested that their only function was to bring the number of objects in the first published version of his catalog (submitted 1771, published 1774) up to 45—possibly simply to beat the number (42) included in Lacaille's 1755 catalog of southern objects.

M43

M43 is a part of the Orion nebula (M42) separated from the main body by a dust lane and sometimes referred to as 'de Mairan's nebula'. It was first discovered in 1733 by de Mairan as a 'brilliance surrounding a star' and consists primarily of a relatively dust free region of ionized hydrogen (H II) and its centrally located exciting star (NU Orionis). Dust mixed with gas lying along or outside the near circular boundary of M43 is important for the energy balance in the region. The Orion A complex consisting of M42 and M43 is the best studied H II region in our galaxy, but work has mainly focused on the central parts and the conditions in the outer gas are not well understood.

M44

M44 is the 'Beehive' or 'Praesepe' (= manger) open cluster in Cancer. Like M42 and M43, this is a very bright (3.5 mag) object known since antiquity. It was first resolved into its component stars by Galileo and contains approximately 350 members. In many ways, such as direction of motion and age (about 700 million years), it is strikingly similar to the nearby Hyades cluster and it has been suggested that both clusters originated in one gaseous cloud. Their x-ray properties are very different, however, possibly because of differences in their binary populations.

Praesepe contains at least four blue stragglers and several δ Scuti stars. The cluster is particularly suited for studies of these stars because of its well-known age and metallicity.

M45

M45 is better known as the Pleiades, a young open cluster in Taurus. Again, this is a very bright (1.6 mag) object known since antiquity. The Pleiades are sometimes referred to as the 'Seven Sisters' since that is the number of stars normally visible to the naked eye. In Greek mythology these represent Pleione and her daughters with Atlas: Alcyone, Asterope (a double star), Electra, Maia, Merope, Taygeta and Celaeno. On a very good night more than 12 of the over 500 mostly faint stars that constitute the cluster can be visible.

The Pleiades were first mentioned by Hesiod (1000 BC) but there are also references in the *Odyssey* (Homer) the Bible and countless other recordings. The name could either derive from Pleione, one of the brighter stars and the mythological mother of the seven sisters, or from the Greek word for 'to sail', since it was during the months that the Pleiades were visible in the sky that the Mediterranean was safe for Greek sailors.

The cluster itself is fairly young (70 million years), consists of a few bright and many faint stars but has such low density that its expected lifetime is not much more than another 250 million years. The bright stars are embedded in nebulous material that reflects the light from them. The brightest of these reflection nebulae is around Merope but they were only discovered from the second half of the nineteenth century onwards, when long-exposure photography became available. More recently still, the bright stars were found to rotate rapidly. Pleione ejected a gas shell in 1938–52, an event that was predicted from the rotation by O Struwe.

Since then, the cluster has been shown to contain a very high number of dwarf members: amongst these are 22 binary systems, three triples and an unusual number of white dwarfs. Their presence in such a young cluster has still not been explained. Additionally, brown dwarfs were found in 1995: these are objects with masses between those of stars and planets and had only been theoretically predicted to exist before they were observed in the Pleiades cluster.

M46

M46 is a moderately rich open cluster in Puppis, in a direction where interstellar distinction is unusually small. It was the first object discovered by Messier after he presented the original version of his list (M1 to M45) to the Academy. It has a total population of over 500 stars and its age has been estimated at 300 million years. It contains several red giants and three eclipsing binaries but has not been at the center of much research so far.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

M47

M47 is an open cluster in Puppis, first recorded (before 1654) by Hodierna. It was independently rediscovered by Messier on 19 February 1771, but he made a sign error when computing its position and so it was considered a 'missing object' (i.e. possibly spurious) until Oswald Thomas clarified Messier's mistake in 1934. It has to be emphasized again that Messier's list, unlike many of the earlier compilations, contains very few mistakes and no spurious objects. Consequently, the confidence in Messier was such that this wrong position survived into the General Catalog by John Herschel who remarked that: 'This cluster has not since been observed. It is probably a very loose and poor one'.

Under good conditions, M47 is visible to the naked eye (5.2 mag). It is a loose, young (78 million years) cluster of bright stars that resembles the Pleiades in its overall stellar population and it can therefore be used for studies comparing the stellar evolution as a function of mass in different clusters.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

M48

M48 is another 'missing object' (see also M47). The open cluster in Hydra was recorded by Messier on 19 February 1771 but an error in the data reduction resulted in a wrong position. The error was cleared up and the correct object identified by T F Morris in 1959. In the meantime, the cluster was independently rediscovered by Caroline Herschel. It has an angular diameter of 54 arcmin and a visual magnitude of 5.5 and can therefore be observed with the naked eye under good conditions. The cluster contains about 80 stars but membership is still not entirely clear and it is thought to be about 300 million years old.

M49

M49 is the brightest elliptical galaxy in Virgo. It was discovered by Messier on 19 February 1771 and was the first member of the huge Virgo cluster of galaxies to be recorded, later followed by two more giant ellipticals (M60, M87). It is less dense than M87 and more yellow overall than most galaxies in the cluster.

Ellipticals are galaxies thought to be in a late stage of their evolution and M49 contains no gas, dust, or star-forming systems but around 6000 globular clusters. These are particularly interesting because they can be shown to fall very strictly into two different age groups. Some theories of galactic evolution predict a large fraction of ellipticals to have been formed by the merging of spiral galaxies, which would naturally produce a younger and an older population of globular clusters within the same elliptical. Ongoing studies of the dynamics attempt to determine whether they are consistent with this picture.

M5

M5 is a globular cluster in Serpens Caput halfway between Arcturus and Antares and 0.5 degrees north of 5 Serpentis. It was discovered by the German astronomer Gottfried Kirch in May 1702 but independently rediscovered by Messier in 1764 (Kirch did not publish his discovery). With a diameter of 130 light-years it is the largest of Messier's globular clusters (although larger ones have since been discovered) and unusually asymmetrical. Its visual brightness is 5.6 mag and its age has been estimated at 13 billion years. Its distance from the Sun is 22 800 light-years.

M5 contains 105 variables the brightest of which can be seen 3 arc minutes southwest of the cluster's centre with simple 25×100 binoculars. A dwarf nova was discovered in 1981. Dwarf novae are small stars that ignite due to the accretion of material from a binary companion. These events are more rare than supernovae.

M50

M50 is a young, open cluster in Monoceros. It was discovered in 1772 by Charles Messier but there is a possible earlier recording by G D Cassini.

The cluster has an age of about 100 million years and about 200 stars in the main body. Some of these are red and yellow giants but studies of the evolution of high-mass stars have not so far included this cluster. The distance has been estimated to be about 940 pc.

M51

M51, the WHIRLPOOL GALAXY in the constellation Canes Venatici, was discovered by Charles Messier on 13 October 1773, when observing a comet. It has a visual magnitude of only 8.4 and is hence difficult to observe as light pollution makes it easily fade into the background. Nevertheless, Lord Rosse in 1845 recognized its spiral structure and it is therefore the first spiral galaxy that was identified as such. M51 has been classified as Sc, a so-called 'grand design' spiral whose spiral arms can be traced through almost three revolutions. It is the dominating member of a small group of galaxies (also including M63) at a distance of about 9.6 Mpc (37 million light-years). Interactions with its close companion galaxy NGC 5195 have possibly caused the strong spiral structure.

The nucleus of this galaxy is heavily obscured by dust but the presence of an AGN (active galactic nucleus) is strongly suggested by the point source of hard x-rays within it. On the evidence of this and on the basis of optical emission lines, the galaxy was classified as Seyfert 2 or LINER (low-ionization nuclear emission-line region—a type of AGN) and most current research on the galaxy centers on the properties of its AGN.

Additionally, the denser parts of the galaxy have been shown by the ISO satellite to harbor star-forming regions and in 1994 a supernova of type Ic was found by the amateur astronomers Jerry Armstrong and Tim Puckett.

M52

M52 is a comparatively rich but poorly studied open cluster in Cassiopeia. Its visual magnitude is 7.3 and it extends over 13′ but is situated in a region of high interestellar absorption which causes a non-uniform reddending across the cluster and renders determination of its age and distance very difficult. Its distance has been variously given as 25 or 150 Mpc and its age is thought to be around 35 million years (or much older with another distance). The cluster contains 193 probable member stars amongst which there are two potential δ-Scuti variables (one of which was confirmed in 1998), three slowly pulsating B stars and one eclipsing binary.

M53

M53 is a metal-poor (i.e. old), moderately compact globular cluster in Coma Berenices, belonging to the outer halo of our galaxy. It is—within uncertainties—identical in age to M92 and very rich in variable stars. M53 has a visible magnitude of 7.6 and a distance of about 56 000 light-years from us or 60 000 light-years from the Galactic Center. There is little or no foreground reddening so the distance is reasonably well determined. The cluster contains 47 known RR Lyrae stars and about 114 blue stragglers in a strikingly bimodal radial distribution similar to M3.

Clusters in the outer halo are particularly interesting for the study of the formation of our galaxy since they are believed in some cases to be older than the galaxy itself (see for example M54).

M54

The globular cluster M54 in the constellation Sagittarius was discovered by Charles Messier on 24 July 1778 and is hence the first extragalactic globular cluster ever to be recorded. It was not until 1994, however, that it was shown not to be a member of our Galaxy but of a very nearby dwarf galaxy SagDEG (the Sagittarius Dwarf Elliptical Galaxy), one of four globular clusters in that galaxy and possibly its nucleus. It has a visual magnitude of 7.6 and since it is at a distance of slightly over 80 000 light-years this makes it one of the most luminous globular clusters known, second only to ω Centauri. It has a metal-poor blue horizontal branch typical of old globular clusters and contains 82 known variables, the majority of which are RR Lyrae. An accurate age analysis has so far not been possible, but it is thought to be between 0.5 and 1.5 billion years older than M68 and M5 (i.e. about 11 billion years) which would make it significantly older than other member clusters and around 3 billion years older than the field (i.e. the non-cluster stars of our Galaxy).

M55

M55 is a large, loose globular cluster in the constellation Sagittarius with a visual magnitude of 6.3 and a diameter of 19′. It was discovered by Lacaille between 1751 and 1752 when he was observing in South Africa but it is difficult to see from the northern hemisphere. Although Messier first looked for it in 1764 he only found it in 1778. M55 is a halo cluster with a high galactic latitude, which means there is little extinction from dust in the galactic plane and its size and luminosity therefore make it a good object for photometric study. It has an extremely blue horizontal branch and its age is thought to be around 14.5 billion years. If this age determination is correct it can be used to put a lower limit on the age of the universe which is thought to be between 10 and 20 billion years. Particularly interesting is its population of 74 blue stragglers, some of which are thought to be members of binary systems. To confirm this would be an important test for current theories of blue straggler formation, most of which involve binary systems.

M55 also contains a low-luminosity x-ray source discovered by the ROSAT satellite.

M56

M56 is a globular cluster in Lyra in a good position for northern hemisphere observers. It has a visual magnitude of 8.3 and an angular diameter of 7.1′ (about 60 light-years at a distance of about 31 600 light-years). The cluster is not particularly rich and its low galactic latitude means that the region is strongly contaminated by field stars (i.e. membership of stars to the cluster is somewhat difficult to establish). It contains two RR Lyrae variable stars, one BL Her, one RV Tauri and three red variables (note that this is the latest count: Helen Sawyer Hogg in the 1940s found 12 variables, among which was a Cepheid that might not be a member).

M57

M57, the 'RING NEBULA', is a planetary nebula in the constellation Lyra. It was discovered by Antoine Darquier de Pellepax and is now considered the prototype planetary nebula in the northern summer sky, even though William Herschel, who invented the term, did not consider M57 a planetary nebula. It consists of a hot (100 000 K) central star surrounded by a ring of dust and gas which is probably some sort of torus and would look similar to the dumbbell nebula M27 if it could be viewed from its equatorial plane. Planetary nebulae are thought to form when an old giant blows off its outer layers, which in this case must have happened in some sort of polar or bimodal form since we are seeing the torus rather than a shell. Recent Hubble images of M57 show subarcsecond dust globules—probably bits of the old star's shell. The hot core left over after the explosion ionizes the gas around it which re-emits the energy in a very few lines (this is very common for planetary nebulae, see also, for example, the description of M27): from the innermost parts of the nebula outwards these are UV radiation, forbidden lines of ionized O and N, and red hydrogen lines. The ongoing chemistry in the nebula is likely to be dominated by photodissociation, shocks and ion–molecule reactions.

M58

M58 is a bright, barred spiral galaxy in Virgo, one of the brightest in the Virgo cluster and one of only four barred spirals in Messier's catalog (the others are M91, M95 and M109). It has excited considerable recent research interest mainly because of indications of an active galactic nucleus (AGN). It was classified as a Seyfert 1.9 or a LINER (low-ionization nuclear emission-line regions—a type of low-luminosity AGN) since it has a flat-spectrum radio core (i.e. the core emits equally across all radio frequencies—this indicates some very high-energy processes) and a point-like x-ray source at its nucleus. However, the LINER ionization source is not clear and the energetics of the nucleus are difficult to explain by current models. The latest attempts center around the possible existence of some sort of ionized accretion disk around the x-ray source.

The galaxy is at a distance of 60 million light-years, has visual magnitude 9.7 and contains two recent supernovae (18 January 1988, type II; 28 June 1989, type I) which represent the other big focus of research in this galaxy.

M59

M59 is an early-type (i.e. old) elliptical galaxy in the constellation Virgo and a member of the Virgo cluster (the nearest cluster of galaxies, much larger than our own Local Group). It is considerably less luminous than M49, M60 and M87 but still one of the brighter elliptical galaxies in the cluster. M59 contains around 2000 globular clusters, easily 10 times more than the Milky Way but much fewer than the three giants above. The galaxy's most interesting feature is its disk component: there are two basic types of elliptical galaxies, one disky, more regular and one irregular, boxy, usually radio-loud with x-ray activity indicating recent mergers. Disk components are thought to be caused by flattening through rotational velocity and hence the recent work on M59 has concentrated on its internal dynamics.

M6

M6 is one of two prominent open clusters in Scorpius positioned in the 'stinger' at the end of the scorpion's tail. Unlike nearby M7, which is seen against a backdrop of rich Milky Way starfields, the surroundings of M6 are relatively star-free. Both clusters are visible to the naked eye as hazy spots but it seems that the first person to establish the true nature of M6 was the Swiss astronomer de Cheśeaux around 1745 before Messier rediscovered it in 1764. The stars of M6 form a shape reminiscent of the outline of a butterfly, from which comes its popular name the Butterfly Cluster. In one of the 'wings' lies its brightest member, BM Scorpii, an orange giant that varies between about fifth and seventh magnitude every 27 months or so. M6 appears somewhat smaller and fainter than M7 since it lies at roughly twice the distance, 1 600 light-years. Its age, though, is only about half as great, some 80 million years.

M60

M60 is a giant elliptical galaxy in the Virgo cluster (see also the mention under M59). It has a diameter of 120 000 light-years and an intrinsic luminosity of about 60 million solar luminosities. M60 contains around 5100 globular clusters (for comparison the Milky Way has about 150). These clusters have been studied intensively since they are very interesting for the formation history of elliptical galaxies: the color of the clusters and their positions in the halo gives some clues as to the heavy-element enrichment process during formation.

M60 is also interesting dynamically: arguments from internal dynamics require a central black hole of 10^9 solar masses. This fits with theories of galaxy formation which predict that all large ellipticals should host black holes left over from an earlier quasar phase.

In the radio part of the electromagnetic spectrum M60 possesses weak jets and radio lobes also indicating an active nucleus. Additionally, its spectrum possibly indicates that star formation was going on until fairly recently which would be highly unusual for such an old galaxy.

M61

M61 is a barred spiral galaxy in Virgo—another large member of the Virgo cluster. It was discovered by Oriani on 5 May 1779 when following a comet. Incidentally, Messier also saw it that night but mistook it for the comet (he was to make the same mistake twice more before he realized that the object did not move and included it in his catalog six years later). The galaxy is at a distance of about 60 million light-years and has a visual magnitude of 9.7. Its core remains unresolved but recent HST pictures showed a nuclear spiral structure of the massive star-forming regions. It is thought that the bar accumulates gas in the nuclear regions, produces the star-forming rings and might eventually generate or feed an AGN.

Three supernovae have been observed in M61: 1926A, 1961I and 1964F.

M62

M62 is a globular cluster in Ophiuchus which Messier discovered in 1771 but for which he determined an accurate position only in 1779 (hence the relatively high number in the catalog). It is at a distance of 21 500 light-years from the Sun, and has a visual magnitude of 6.5. Its distance from the galactic center is only about 6100 light-years and hence its irregular shape is probably due to deformation by galactic tides. It is very similar to M19, its apparent neighbor, in size and magnitude. Research interest in this cluster has centered on its 89 variable stars. These are mostly RR Lyrae and 74 periods have been determined. It is interesting to note that M19, in spite of its similarity, only has four variable stars.

M63

The 'Sunflower' spiral galaxy M63 in Canes Venatici was discovered by Messier's collaborator Pierre Mechain, on 14 June 1779. It is in a physical group with M51 and several smaller galaxies and represents the archetypical example of the class of galaxies known as 'flocculent spirals'. In these galaxies, the visible spiral structure is patchy and localized, formed by low-amplitude density waves. It is not clear whether they are simply weak counterparts to the grand-design spirals or whether they are dynamically different. M63 exhibits a weak two-arm structure in the near-infrared and structures similar to the giant molecular associations of the grand design spirals M51 and M100 have been detected.

M63 also has a mildly active nucleus and a supernova was observed in May 1971.

M64

M64 is a spiral galaxy in Coma Berenices sometimes called the 'BLACK EYE' or ('Sleeping Beauty') galaxy, because of the conspicuous dark dust structure near its center. It is at a distance of roughly 12 million light-years but close to the Virgo cluster, which makes its recession velocity almost certainly dominated by infall (and hence renders the distance uncertain). M64 has attracted a lot of interest because of its very unusual dynamic structure: it has an inner disk of gas and stars and a counter-rotating outer disk which is mostly gas. The dust lanes of the 'black eye' are in the inner disk. The two disks are coplanar to about 7 degrees. The transition region between them is not in a steady state and contains vigorous star formation. Originally, it was thought that this bizarre two-disk system was produced by the accretion of a companion galaxy, but even that model does not fully explain the dynamic behavior and it also fails to explain why systems like these are so very rare (only three galaxies with counter-rotating disks have been discovered so far).

M65

M65 is a spiral galaxy in Leo, part of the Leo triplet which consists of M65, M66 and NGC 3628. Its distance has variously been determined as 6.7 Mpc (de Vaucouleurs 1975) and 23.4 Mpc (Sandage and Tamman 1975) but the lower value is generally considered more likely since it seems more consistent with H I studies. The galaxy shows a prominent dust lane on the facing edge with some possible star-formation regions close to it. The stellar population in the disk is smooth and old. The triplet system is very tightly gravitationally bound (see also the description of M66) but that does not seem to have had any effect on the star formation rates of any of the member galaxies. Equally, the spiral arms of M65 have remained tightly wound so far, without any indication of tidal disruption.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

M66

M66 is a spiral galaxy in Leo and also part of the Leo triplet consisting of M65, M66 and NGC 3628. The close association between this galaxy and NGC 3628 could be responsible for the disturbed nature of the entire system. M66 is larger than M65 without a well-defined central bulge and very deformed spiral arms. A tidal tail extends from NGC 3628 into the direction of M65 and the two galaxies are linked by a bridge of neutral hydrogen. This clearly indicates a recent close encounter which is thought to have triggered some unusual dynamic processes in M66, such as the central concentration of stellar and gas mass and the formation of a gaseous bar. This bar causes an efficient radial mass accretion across the entire disk and the galaxy is thought by some to be evolving into an AGN (active galactic nucleus). It has an H_1/H_2 mass ratio that is close to Seyfert galaxies and seems to be currently undergoing at least a weak form of nuclear starburst.

Three recent supernovae have been observed in M66: 1973R, 1989B and 1997bs.

M67

M67 is an old open cluster in Cancer, the oldest in Messier's catalog at about 4 billion years and still one of the oldest known. It is well studied since it is comparatively rich for an open cluster, at a distance of only 4000 light-years from the Sun and with a high galactic latitude (i.e. there is little reddening or dust extinction). The population of M67 (around 500 stars, at least 38% of which are binaries) serves as a paradigm for studies of structure and evolution of population I solar-age stars, just as Hyades and Pleiades do for younger objects. It has a very well developed population of red giants and some blue stragglers (a further indication that the phenomenon of blue stragglers—hot, young stars in a predominantly old population—is in some way connected to a high incidence of binary associations).

M67 has also been used for extensive comparisons of the evolution of cluster and field stars.

M68

M68 is a very metal-poor globular cluster in Hydra, very similar to M30. It is a large and loosely spread object at high galactic latitude and has been studied mainly for its age and its metallicity. It is thought to be around 13 billion years old (i.e. identical in age, within the errors, to M15), but the exact metallicity is difficult to determine since the indicators lose sensitivity at the low end. However, it is not quite metal-poor enough to consist of population III (i.e. primordial) stars.

The stellar population of M68 is predominantly old with a gap in the horizontal branch of the HR-diagram very similar to that in M15: the eight bluest stars are clearly separated from the remainder of the horizontal branch.

M69

M69 is a metal-rich, globular cluster in Sagittarius, which was originally thought to be a 'disk' cluster, i.e. a member of the subsystem of globular clusters in the galactic disk. However, the distinction between disk and halo clusters is controversial and never very clear. M69 can also be regarded as a halo cluster with a very eccentric orbit. Additionally, it has the age and metallicity of a typical halo cluster.

The cluster was discovered by Lacaille. Messier first missed it in 1764 (the object is small and faint and becomes more difficult to observe further north) but found it with a better telescope in 1780. It has a bright and compact core with eight known variables. A possible (but still unconfirmed) cataclysmic binary was discovered in 1986.

M7

M7 is an open or galactic cluster in the constellation Scorpius. It is easily visible with the unaided eye some degrees northeast of Shaula (λ Scorpii) and was first mentioned by Ptolemy in AD 130 (his mention might also include the nearby M6). Hence the cluster is often referred to as 'Ptolemy's Cluster'. It was included in the published lists of nebulous and stellar objects by Hodierna (around 1654—counted 30 stars), Halley (1678) and by the Abbé de la Caille (1755—counted '15 or 20' stars).

M7 contains about 80 stars of magnitudes greater than 10 (the brightest is a yellow giant). Its overall visual brightness is 4 mag and its diameter is 18 light-years. The age was estimated at 220 million years (note that Koelbloed gives a much lower value of 70 million years) and the distance to the Sun as 800 light-years.

M70

M70 is a globular cluster in Sagittarius at a distance of about 28 000 light-years. It has a southern declination and is therefore difficult to observe from the northern hemisphere but it is a bit more luminous and bigger than its apparent neighbor M69. For a globular cluster it is of only intermediate metallicity and it has a very pronounced blue straggler sequence. The far-UV light is smoothly distributed and not dominated by a single bright star, it is therefore not entirely clear what causes the strong emission in that region. There are only 10 variable stars, all of which are RR Lyrae.

M71

M71 is an unusual globular cluster in Sagitta in that it is very metal rich (only M69 is richer) and very sparse. For a long time its classification was undetermined between a sparse globular cluster and a very dense open cluster. It is, however, now generally thought to be a globular cluster. Its second unusual feature is its very low-eccentricity orbit. Globular clusters usually move around the galactic plane in the halo, but there is a population of metal-rich clusters which are concentrated close to the plane. M71 belongs to these and has been studied carefully in order to gain more insight into the process of cluster formation. Interestingly, its stars seem to have a very varied abundance of some of the heavier elements which might indicate that the gas from which they were formed was not properly mixed. Unlike most globular clusters, M71 has only a very few variables. Eight have been identified so far, none of which are of the common RR Lyrae type.

M72

M72 is a globular cluster in Aquarius, not very concentrated, quite distant but intrinsically very luminous. It hosts 42 known variable stars and is part of a small group of globular clusters together with NGC 6584, NGC 6864, M75 and others. This group has been the focus of some interest since it has a high apparent retrograde motion around the galactic center. The significance of a group of apparent retrograde clusters lies in the hypothesis that clusters of the galactic halo formed in relatively large satellite galaxies which subsequently merged with the Galaxy to become the galactic halo.

M73

M73 is an asterism of four stars which was recorded by Messier only as a help for the determination of the position of M72 (which is 1.5 degrees to the west). It is not entirely clear whether the group is a real cluster rather than a mere asterism. E M Arnal classified it as an open cluster in 1979, but this assertion does not seem to have been checked.

M74

M74 is a spiral galaxy in Pisces with a linear diameter of 95 000 light-years (i.e. of roughly the size of the Milky Way) and a visual magnitude of 9.4. In many ways, this is a prototypical 'grand design' spiral. Its arms are about 1000 light-years broad, it has a very small and bright nucleus and is particularly beautiful on photographs because it is face-on. As well as its normal appearance, however, it has been shown to have a very extended disk of neutral hydrogen with a complex velocity structure (i.e. it is slightly warped). The velocity field in the outer disk is inconsistent with differential rotation in a flat disk. The galaxy also exhibits some irregularities in its otherwise smooth and regular spiral arms. A recent merger event (or recent merger events) has been postulated to explain this behavior but no suitable candidate can be discerned in the vicinity.

M75

M75 is a globular cluster in Sagittarius at a distance of 57 700 light-years (i.e. beyond the Galactic Center). It is compact and has a very high luminosity (about 160 000 solar luminosities). It is a member of the same group as M72 and therefore has an apparently retrograde orbit around the Galactic Center. Like most globular clusters with a high degree of concentration and a relatively high metallicity, it has a fair number of variable stars (10 RR Lyrae, six with known periods) and some radio sources.

M76

M76 is a planetary nebula in Perseus, often called the 'LITTLE DUMBBELL NEBULA' (or the 'Cork' or 'Butterfly' Nebula). It was assigned two NGC numbers since it was originally thought to be two distinct objects. Like most nebulae, it has a very ill-defined distance: estimates range from 1700 to 15 000 light-years. The bright part consists of a slightly elliptical ring that is pointing towards the observer (i.e. it is viewed nearly edge-on). Attached to that ring are two inner lobes (the wings of the butterfly) and fainter outer lobes which move at a much lower expansion velocity. Additionally, there is a polar cap on the southeast side, which has a higher expansion velocity again. The nature of these outer lobes and the polar cap remains unknown, but it is generally thought that the nebula was probably formed by some interaction of stellar winds. The central star has been identified and has a temperature of about 60 000 K.

M77

M77 is a spiral galaxy in Cetus, at a distance of about 60 million light-years and with a diameter of between 120 000 and 170 000 light-years. It belongs to the class of galaxies known as 'Seyfert galaxies', i.e. it has a brilliant nucleus with intense star-forming activity in a disk around it, an emission-line spectrum and fairly faint spiral arms. Seyfert galaxies themselves are a particular type of AGN (active galactic nucleus) galaxy. Most of these have (or are thought to have) a supermassive accreting object at the center that powers the intense luminosity of the object. In the case of M77 this object is thought to have about 10^7 solar masses. Recent research interest has mostly centered around the central object and the star-formation activity in the disk. M77 has the most luminous water-vapour maser yet reported (350 solar luminosities) which indicates an ongoing burst of star formation. But because of its brightness, proximity and favorable orientation, the galaxy in general provides a good laboratory for studying the Seyfert nucleus, inner disk and circumnuclear ring.

M78

M78 is a reflection nebulosity seen against the Lynds 1630 dark cloud and appears to be associated with the Orion complex. It contains many bright, hot B stars which are probably very young and about 45 variables have been identified in or near the nebula. For this reason, M78 is also sometimes referred to as a 'young embedded cluster' and has been important for the study of stellar evolution. Its visual structure is dominated by a band of dark obscuration that delineates the northern edge of the nebula. It resembles a faint comet. Its distance has been estimated at 1600 light-years and its visual magnitude is 8.3.

M79

M79 is a globular cluster in Lepus, at a distance of about 41 100 light-years. It is moderately metal-poor (metallicity comparable to M13) but has an extremely blue horizontal branch and generally shows more UV bright objects than would be expected for such a cluster. It has been speculated that there could be kinematic processes changing the stellar evolution and M79 is sometimes regarded as a possible instance of core collapse because of the irregularity of its profile and the fairly high concentration. It is slightly elliptical and contains seven known variables.

M8

M8 is a diffuse nebula also known as the 'LAGOON NEBULA' because of the dark band separating it into two bright parts. The nebula is associated with an open star cluster (NGC 6530) which can be seen with the naked eye in the constellation Sagittarius to the southeast of the bright nebula M20. The cluster was first discovered by Flamsteed around 1680 (he was the first Astronomer Royal and published a star catalog *Historia Coelestis Britannica* in 1712). The French Astronomer Le Gentil described the nebula in 1747.

The open cluster was created by star formation by the collapsing gas in the nebula and most of the interest in this object centers on the fact that star formation can still be seen to occur. The nebula is rich in substructures, notably the dark globules (which are collapsing protostellar clouds) and the recently discovered twisted-rope structures which are possibly tornado-like phenomena caused by the large difference in temperature between the hot surface and the cold interior of the clouds combined with the pressure of starlight. Within its brightest part, there is a region known as the 'HOURGLASS NEBULA' where star formation appears to take place currently. The bright emission of this part (and the emission in the rest of the nebula) is caused by the gas re-emitting radiation that was absorbed from the very hot young stars. The open cluster contains between 50 and 100 of these with a large number of irregular variable stars such as 'flare' stars (type UV Ceti). Its age is estimated to be just 2 million years. The nebula has a diameter of 140 light-years and is about 5 200 light-years away from the Sun. Its visual brightness is 6.0 mag and it also emits radio waves in the 9.4 cm band.

M80

M80 is a globular cluster in Scorpius that is unusual for two reasons (which may be related). In May 1860 a dwarf nova occurred in the cluster possibly caused by a cataclysmic variable. Dwarf novae are rare events in globular clusters (see also M14). M80 also has the largest and most concentrated population of blue straggler stars (which are now thought to be a late stage in the evolution of a close binary system) ever observed in a galactic globular cluster. This may suggest that it is in a transient dynamical state during which stellar interactions are delaying the core-collapse process.

The distance to M80 is not very well determined and varies between 27 000 and 36 000 light-years. Its visual magnitude is 7.3 and its diameter is 8.9′.

M81

M81 is an early-type spiral galaxy with a prominent bulge and well-defined arms. It is sometimes also known as 'Bode's Galaxy'; it is very bright, and can under good conditions be seen with the naked eye in the constellation Ursa Major. Together with M82 it forms a small group and there are some indications that the two have had a close encounter in the past (M82 seems to have been affected more—its shape is more irregular than that of M81). With a distance of only 12 million light-years, M81 is a fairly nearby galaxy and has therefore been extensively observed. It has a dense and unresolved core which emits strongly in the radio waveband as well as hosting an x-ray source. This, together with other indications, such as low-ionization emission lines, has led to the conclusion that the core of M81 must also host a low-luminosity AGN (active galactic nucleus). As is usual with these phenomena, the details of the object generating the power in the center are not well understood. But it is clear that M81 shows features similar to a weak Seyfert galaxy.

M82: The Starburst Galaxy

The nearby irregular galaxy M82 drew the attention of observers decades ago owing to its spectacular appearance, which suggested that it was an 'exploding' galaxy. The appearance of an explosion derives from the consequences of the enormous amounts of star formation activity in this galaxy. Intense star formation events in the central regions of galaxies, known as the starburst phenomenon, may be a common part of galaxy evolution, so the study of M82, the prototypical STARBURST GALAXY, is of particular importance. The STAR FORMATION is associated with a very rich interstellar medium with large amounts of molecular gas, dust and ionized gas as well as x-ray-emitting plasma. These are extremely unusual conditions in a galaxy, which raises the question of its origin as well as of its evolution and eventual fate.

The galaxy M82 is a disk galaxy several times smaller than the Milky Way and in one of the closest groups (3.6 Mpc), whose three brightest members are M81, M82 and NGC 3077. There appears to have been a tidal interaction between the members of the group that has torn neutral hydrogen from the outer parts of M81 and M82. This interaction, which took place about 10^8 yr ago, has perturbed the inner part of M82, probably producing the stellar bar in the bulge region. The presence of the bar and the tidal disturbance of the gaseous disk have led to the inflow of gas from the disk to the central 1 kpc of the galaxy. This buildup of gas occurred fairly quickly and it led to a period of rapid star formation that has occurred in a relatively small region. The energy released by the multitude of massive stars produced a superbubble of hot gas that has broken out of the disk and is flowing rapidly away from the galaxy.

Central star formation activity

The most direct evidence for star formation comes from the identification of the many young STAR CLUSTERS in the central region. Many of these star formation regions are obscured by dust, but, despite this limitation, HUBBLE SPACE TELESCOPE imaging reveals nearly 100 star clusters which have a typical size of 3 pc and a typical luminosity of several million solar luminosities, which exceeds that of any of the famous star formation regions in the Milky Way and even the most luminous star-forming cluster in the Large Magellanic Clouds. These star clusters are so dense that they are most similar to GLOBULAR CLUSTERS, although in these environments they will most likely become tidally disrupted rather than becoming long-lived gravitationally bound units. These clusters can occur in associations, with at least 45 such clusters found in one region alone. The optical observations set a lower limit to the actual number of clusters since dust extinction hides many clusters. Observations at some wavelengths are not affected by dust extinction, such as radio continuum and line observations. The continuum observations are sensitive to some of the SUPERNOVAE that occur, which should be associated with the young star clusters, but none of the radio supernovae coincides with an optical cluster. If the radio supernovae are randomly distributed in young star clusters, then the lack of coincidence with the optical clusters implies that they must be associated with optically obscured star clusters. These obscured star clusters would have to be 20–40 times more common than the optically visible clusters in order to satisfy the statistical result that the supernovae do not coincide with visible clusters.

The rate of star formation and the length of time over which the starburst has occurred are not determined by direct studies of the star clusters, but rather from the studies of the emission by the interstellar medium. Of the total luminosity produced by M82, 84% is emitted at wavelengths longward of 3 μm, and this is dominated by reemission from dust. The dust absorbs the ultraviolet light from the young stars and it is heated to a temperature of about 45 K. At this temperature, most dust grains emit like black bodies or gray bodies with a peak emissivity at about 60 μm. Some smaller dust grains are heated to higher temperatures owing to non-equilibrium effects, emitting at wavelengths as short as a few microns. However, the smallest dust components, the poly-aromatic hydrocarbons, are probably destroyed by the intense ultraviolet radiation field, since their infrared spectral signatures are absent.

Because of the heavy obscuration in the optical region, the infrared lines are the most useful diagnostics of the conditions within the star-forming region because the optical depth in the 50–157 μm range is less than 0.1. Both moderate-ionization lines ([O III] λ 51.8 μm, λ 88.4 μm, [N III] λ 57.3 μm) and low-ionization lines ([O I] λ 63.2 μm, λ 145.5 μm, [C II] λ 157.7 μm) have been measured by the Kuiper Airborne Observatory as well as by the Infrared Space Observatory. The moderate ionization lines are typical of H II REGIONS, so their luminosities and the line ratios give direct insight into the number of ionizing photons as well as the photon-to-gas density ratio. Strong low-ionization lines are not found in classical H II regions, but they are typical of photodissociation regions, where the ionizing radiation is dissociating the molecular gas and heating it, eventually becoming part of the H II region. Models for this emission indicate a star formation rate of $10 M_\odot$ yr^{-1} and a relatively young age for the starburst, (3–5) $\times$ 10^6 yr, and a mass of young stars of $10^8 M_\odot$. Several factors, such as the dynamics within the core and the superwind of the starburst, point to an age several times greater ((1–2) $\times$ 10^7 yr), and this longer age is probably the more reliable one. This longer age can be reconciled with the age inferred from the star formation rate if the young star clusters have an excess of high-mass stars (a flatter initial mass function), although this point is controversial. The star formation rate emphasizes the extreme nature of the starburst phenomenon: about 3 times the total star formation rate of the Milky Way occurs within just a few hundred parsecs of the center of M82, 10^{-4} of the surface area of the Milky Way.

The stars are forming from the plentiful molecular gas in the core, which has been the subject of numerous

studies, both with single dish and synthesis array telescopes and in several transitions of a variety of molecules. These studies indicate that there is about $2 \times 10^8 M_\odot$ of molecular gas in an irregular ring that is in circular or elliptical orbit about the center of the galaxy. The star formation efficiency for this gas has been quite high, about 30%, given the estimate for the mass of young stars, $10^8 M_\odot$, and roughly 30 times higher than the typical star formation efficiency in the disk of the Milky Way.

The ensemble of young stars has several effects on the environment from which they formed. In addition to the photodissociation and H II regions produced by the ultraviolet photons, stellar winds and supernovae are extremely important in shaping the interstellar gas. Fast stellar winds from massive stars will create a hot bubble in a uniform medium along the lines of the classic superbubble scenario. At the end of the life of a massive star, the supernova event deposits about 3 times as much energy as the fast wind, eventually dominating the dynamics. The supernova rate is estimated to be about one supernova every 10 yr, 3–10 times greater than that for the entire Milky Way, but confined to this relatively small region. The frequency of supernovae is large enough that it is appropriate to treat the energy deposition as an input of energy that is smooth in time. To follow the response of the gas to this energy input, numerical hydrodynamic models have been used, assuming a locally uniform medium with a decreasing density out of the disk. These models show that, in the early stages, a spherical hot bubble develops, but, as the bubble size becomes comparable with the disk thickness, it begins to elongate perpendicularly to the disk, along the direction of the steepest density gradient. As the shock proceeds along the density gradient, it changes from a decelerating shock to an accelerating one. For the usual decelerating shock, the dense shell that has been formed is stable, but, with an accelerating shock, the dense shell is subject to the growth of Rayleigh–Taylor instabilities and it breaks up. This leads to the rapid outflow of material from the galaxy, discussed below.

Various aspects of this hydrodynamic phenomenon are seen at several wavelengths, both in the active star-forming region as well as in the flow extending from the disk. In the position–velocity diagram for ^{12}CO(1–0, 2–1), ^{13}CO(1–0) and ^{18}CO(1–0), there is an absence of emission at ± 45 km s^{-1} for a region about 80 pc in diameter (figure 1). These observations indicate the presence of a ring of expanding molecular gas of radius 65 pc around a region where the molecular gas has been destroyed. The destruction of the molecular gas was probably due to a combination of ionizing photons, fast stellar winds and supernovae, but the expansion velocity of the molecular gas is probably due to the supernova shocks. There is also an absence of radio continuum emission in a region roughly coincident with the CO hole, although there is the possibility that free–free absorption by the ionized gas has dimmed the radio continuum.

The x-ray emission reveals only three point sources in the central region, none of which is coincident with any of the radio point sources or the optical clusters. However, x-rays are dominated by more diffuse emission, which is brightest in the central region and most likely fills the central hole in the molecular gas. This emission appears to consist of multiple components with emission lines, and one decomposition consists of a hard, a medium and a soft component. The soft and possibly the medium component are probably emission from a hot plasma of temperature 0.3 keV and 1.0 keV. The presence of the line emission from eight different elements (from ASCA) plus the diffuse nature of the emission (from ROSAT) indicate that the radiation is produced by hot dilute gas (density of $\sim$0.1 cm^{-3}, temperature of 10^7 K), although of subsolar metallicity. The metallicity of the stars in M82 is subsolar, as expected for a modest-size galaxy, but the metallicity of the gas was expected to be considerably greater owing to the many supernovae that have occurred. Determination of the metallicity in the x-ray-emitting gas with ASCA is not simple because of multiple temperature components and unresolved point sources. Yet it is unlikely that the metallicities are grossly in error, with the largest metallicities occurring for S and Si (0.4–0.5 of the solar value), while Ne and Mg have abundances near 0.2 of the solar value and O, N and Fe have metallicities less than 0.1 of the solar value. These abundance ratios are perplexing, since they do not correspond to those expected from either type of supernova, and it will be interesting to see whether the combination of high spatial resolution and good spectroscopy (from the CHANDRA X-RAY OBSERVATORY) will confirm the abundances.

Finally, the x-ray observations require a hard component (approximately 14 keV if it is a thermal plasma), which is found to vary on a timescale of days and has a luminosity that can approach 10^{41} erg s^{-1}. This seemed unlikely to have a stellar origin, and this led to the suggestion that a supermassive compact object was

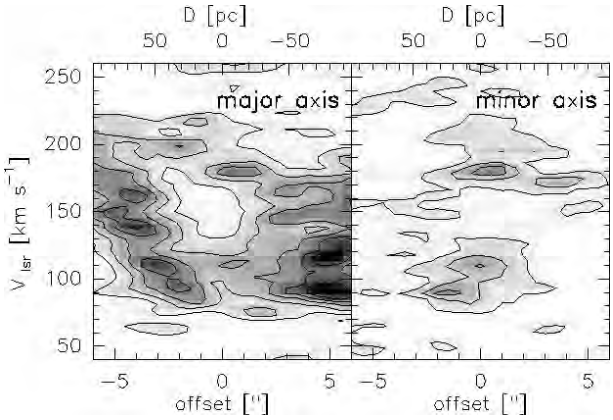

Figure 1. Position–velocity diagrams for the ^{12}CO($J = 1$–0) transition along the major and minor axes of M82. The intensity in the line is proportional to the darkness, so the light region in the center indicates a hole in the molecular distribution surrounded by an expanding molecular ring (from Weiss *et al* 1999 *Astron. Astrophys.* **345** L23).

present, such as a black hole, with a mass in excess of $500M_{\odot}$ if it emits below the Eddington luminosity. This might be thought of as a tiny ACTIVE GALACTIC NUCLEUS, possibly activated by the abundant gas in the central region. From energetic considerations, this nuclear source has little influence on the development of the starburst, which has a bolometric luminosity that is 3 orders of magnitude greater (8×10^{43} erg s^{-1}). The infrared line ratios also are sensitive to the presence of an active galactic nucleus, whose hard radiation will produce high excitation lines. However, the observed ratio of the high- to medium-excitation lines is particularly low in M82 (there is only an upper limit to [Ne V]/[Ne II]), confirming that an active galactic nucleus is either absent or unimportant. Insight into the presence of a central black hole will be provided by the new generation of x-ray telescopes, and Chandra observed M82 during the first few months of operation. X-ray emission from a strong central component was not discovered, confirming the absence of a strongly emitting active galactic nucleus and indicating that the hard emission is most likely caused by another mechanism.

The superwind

The outflow of gas from the star-forming region is observed in several wavebands and it was expected from models as well. The first indication of an outflow came from the study of colors and emission line images in the 1960s, where filaments were seen aligned with the minor axis and extending to at least 3 kpc from the center of the galaxy. These initial studies included spectroscopy of the emission line filaments, which clearly showed recession velocities from the galaxy of hundreds of km s^{-1}, with the exact value depending on the adopted inclination correction, which is substantial since the minor axis of the galaxy is only 8°–9° from the plane of the sky. Whereas many of the basic elements were identified in these observations, more detailed optical emission line studies along with x-ray investigations have given greater insight into the phenomenon.

Optical emission line studies have been carried out with Fabry–Pérot observations, long-slit spectroscopy and narrow-band imaging. These efforts reveal that the outflow on either side of the galaxy is not quite aligned with the minor axis and has a deprojected outflow velocity of 500–800 km s^{-1}. For lines of sight through these outflow regions, the emission lines are bimodal, which is interpreted as the near and far sides of the outflow region (lobes or cones) expanding laterally with a velocity of about 150 km s^{-1}. Close to the galaxy, the emission lines are generally of low ionization, consistent with photoionization from the hot stars in the galaxy. However, in the outer region (beyond 1 kpc), the relative strength of high-ionization lines increases, such as that from [O III], which is unexpected for photoionization, but consistent with collisional ionization from shocks. Beyond 3 kpc, the optical emission line gas becomes generally undetectable, with the exception of a filament 11 kpc from the galaxy and

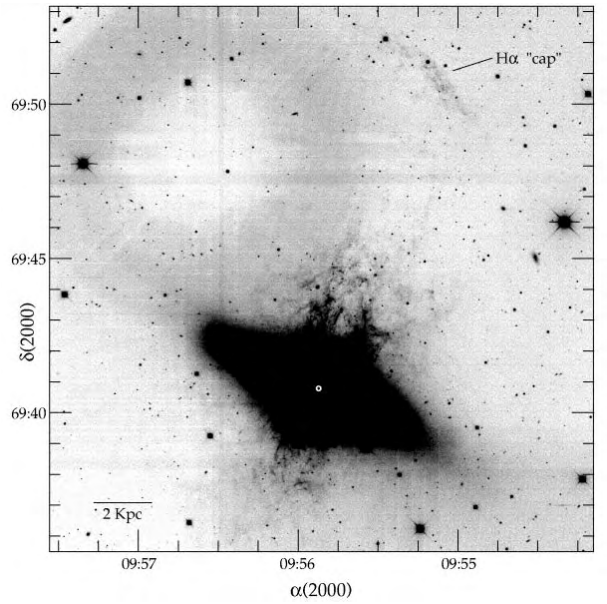

Figure 2. An image of M82 taken in the light of the hydrogen line Hα. The 'donut' on the upper left is an artifact of the corrective optics. The Hα filaments that extend upward from the center trace the breakout and the outflow of the superwind. The Hα cap to the top of the figure is 11 kpc from the galaxy and is probably produced by an impact between the superwind and tidal debris, present before the starburst event (from Devine and Bally 1999 *Astrophys. J.* **510** 197).

with an orientation that is nearly at right-angles to the flow direction (see figure 2). The most likely explanation for this filament is that it represents the interaction of the outflow of material with the cold gas that has been torn from M82 and M81 in their tidal interaction. The strongest support for this interpretation comes from the x-ray observations (the PSPC on ROSAT), which are coincident with the optical emission. The shock interaction between the outflowing gas and slow-moving tidal debris would lead to both the production of soft x-rays and optical emission line excitation. From the temperature of the x-ray emission (10^7 K), a velocity of 800 km s^{-1} is inferred, which is similar to that inferred from the optical emission lines closer to the galaxy. With this velocity and the projected distance, a minimum timescale of 14×10^6 yr is inferred for the time since the breakout of gas from the nuclear region.

The x-ray emission (from ROSAT) is coincident with the optical emission line gas in the inner region, but it extends beyond the optical emission, being visible to about 6 kpc on both sides of the galaxy (plus the additional separated emission 11 kpc from the galaxy on one side) (see figure 3). The temperature of the extended flow regions is approximately 0.5 keV (6×10^6 K), with only a weak decrease in the temperature with distance along the outflow (from 0.6 keV to 0.4 keV). This is a critical measurement for understanding the flow, since, if adiabatic expansion controlled the temperature of the gas as it flowed outward, the temperature would drop far

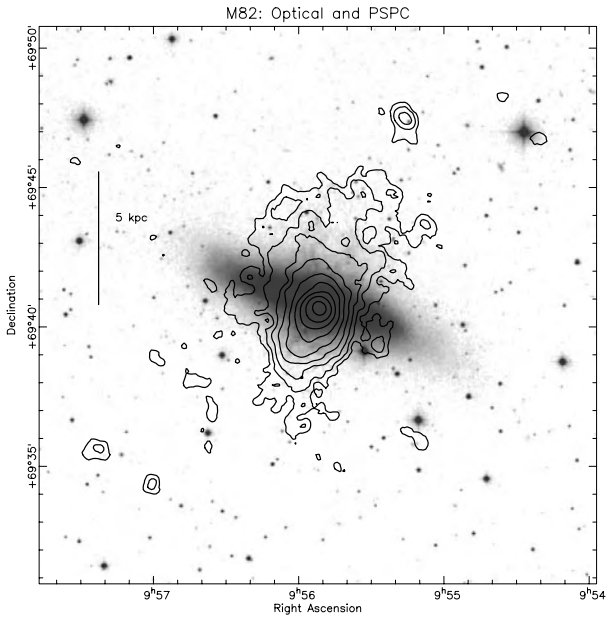

Figure 3. Contours of the x-ray intensity, obtained with the PSPC on ROSAT (0.1–2.4 keV, 30″ resolution), is superimposed upon an optical image of M82. The intense emission from the central region is from the hot gas, while the extended emission perpendicular to the disk, due to the superwind, probably results from an interaction between the superwind and halo gas (from Strickland, Ponman and Stevens 1997 *Astron. Astrophys.* **320** 387).

more rapidly than is observed. The alternative model that has developed posits that a gaseous halo surrounds M82 prior to the starburst event. Following the breakout of the hot gas from the disk of the galaxy, the superwind of hot gas shocks with the halo gas, converting kinetic energy to thermal energy. In this picture, the thermal energy carried by the outflowing gas is unimportant compared with its kinetic energy, which is not subject to adiabatic losses. This also helps to solve the metallicity problem, since most of the emission originates in gas that is characteristic of the pre-starburst supernova, which, for a low-mass galaxy like M82, is subsolar.

In addition to the interaction of the hot gas with a halo environment is the issue of whether the outflow entrains gas, such as for the region close to the galaxy. A determination of the mass flux of the superwind places it at several times greater than that expected from the ensemble of supernovae, suggesting that there has been 'mass loading' of the flow. In this context, mass loading is the process whereby mass is added to the superwind by processes other than the normal shock heating of gas by supernova blast waves. Mass loading is most likely to occur in one of two ways: by the conductive evaporation of cold clouds or by turbulent mixing of cold gas into the hot flow. Conditions are also favorable for conductive evaporation to occur because we know that plentiful molecular gas is close to the hot x-ray-emitting gas. However, efficient conductive evaporation requires magnetic fields that are simply connected between the hot and cold phases, and whether this criterion is met is unknown. Conditions are suitable for turbulent mixing because there is a large differential velocity between the cold gas and the hot superwind. This will lead to the growth of Kelvin–Helmholtz instabilities, producing tongues of cold gas that will mix with the hot gas (shocks will accompany this process). In this case, it remains to be seen whether the rate at which gas can be mixed into the flow is adequate.

A final issue is whether the superwind will eventually fall back to the galaxy or whether it will escape the gravitational field of M82 and become part of the intergalactic medium. The characteristic rotational velocity of M82 is only 100 km s^{-1}, and it is declining with radius, so the escape velocity is unlikely to be greater than 200–300 km s^{-1}, which is significantly less than the velocity of the superwind, 500–800 km s^{-1}. In the outermost region of the wind, 11 kpc from M82, the escape velocity is probably only 50–150 km s^{-1}, so even the cold shocked material is unlikely to be bound to the galaxy. These comparisons indicate that the superwind will remain unbound to the galaxy and will pollute the surrounding medium. If starburst events are common in galaxies, this will be an important means of enriching the intergalactic medium.

Future directions

The nearest starburst galaxies, M82 and NGC 253, have been fundamental to our understanding of the starburst phenomenon, and we look to further studies to settle the outstanding questions. One of the central issues is how the star formation is initiated. Although star formation is occurring in the disk of M82 on kpc scale, it is extremely elevated in the central region, where it has evacuated a hole in the molecular disk. This star formation may propagate outward by creating high-pressure hot x-ray-emitting gas that compresses the cold molecular gas. Current observations show that conditions exist for this to take place, in which case we should see a progression in the age of star clusters as a function of radius in the nuclear region. The detection of these star clusters will require high-angular observations in the infrared region in order to reduce the extinction. This will require observations from NICMOS on the Hubble Space Telescope and subsequent observations with the Next Generation Space Telescope (see INSTRUMENTATION: NEXT GENERATION SPACE TELESCOPE). Also, these observations will identify star clusters that are obscured at optical wavelengths, permitting us to determine whether the radio supernovae are indeed associated with star clusters. These observations should help resolve the issue of whether the star formation produces relatively high numbers of high-mass stars.

Regarding the superwind, there are several outstanding problems that will be addressed with the x-ray telescopes Chandra and the X-RAY MULTI-MIRROR MISSION (XMM).

The central region is tremendously complex, containing point sources, line and continuum emission from hot gas, along with partial absorption by cold gas of widely varying column densities. The high angular resolution of Chandra will be essential in separating these aspects of the emission and determining the basic conditions in the hot gas, such as the temperature, pressure and metallicity. These observations will help us to understand the role that the hot gas has in triggering further star formation in the center and in transforming the cold molecular environment into a hot x-ray emitting medium. Another issue is the degree of entrainment of material in the superwind flow, which would produce a metallicity gradient along the flow, and this will probably best be determined by XMM observations, since sensitivity rather than angular resolution is paramount. Finally, the extent of the wind and its effect on polluting the local environment is an important but challenging issue. The maximum observable extent of the x-ray superwind will be measured by XMM, but that determination may be limited by the low surface brightness of the emission relative to the background. Nevertheless, the future of the field will be very exciting and major advances should occur in the next few years.

Bibliography

The literature is extremely extensive for M82, so I have chosen some of the most recent publications in their areas, which reference the important works that preceded them.

The star clusters that are seen in the central region are discussed by

O'Connell *et al* 1995 *Astrophys. J.* **446** L1

The molecular content in the galaxy and the molecular superbubble are discussed by

Weiss *et al* 1999 *Astron. Astrophys.* **345** L23

The x-ray imaging and temperature studies are thoroughly described by

Strickland D K, Ponman T J and Stevens I R 1997 *Astron. Astrophys.* **320** 378

Models for the breakout and the superwind may be found in

Suchkov *et al* 1996 *Astrophys. J.* **463** 528

M83

M83 is a spiral galaxy of type SABc (i.e. it is an intermediate type between a barred spiral and a normal spiral galaxy) in Hydra (sometimes referred to as the 'Pinwheel Galaxy'). It was fist discovered by Lacaille during the time he spent at the Cape of Good Hope (1751–2) and is therefore the first galaxy beyond the Local Group to be discovered. Its distance is estimated at 15 million light-years, which makes it also the nearest barred spiral.

M83 is a typical example of what is known as a 'starburst galaxy'. Starbursts are areas having very high star formation rates caused by the fast transformation of gas, the violent interaction of stars with the interstellar medium through ionizing fronts, stellar winds and the high rate of supernovae associated with a young stellar population. The origin of the phenomenon is not well understood but it is important for galaxy evolution. Most starbursts are associated with AGN (active galactic nuclei) as well as high-density gas and a non-symmetric gravitational potential usually due to a bar or an interacting galaxy. M83 is typical in that it has a bar as well as a suspected AGN.

Together with NGC 5128 and NGC 5253, M83 forms a small group. Both of these other galaxies are peculiar, which may indicate a previous interaction. Six supernovae have been reported so far—more than in any other Messier object.

M84

M84 is a lenticular galaxy in Virgo at a distance of approximately 60 million light-years. It is populated by old yellow stars and has a system of globular clusters (much less dense than that of M87). It also has a rapidly rotating nuclear gas disk and hosts an AGN (active galactic nucleus) that is most likely powered by a supermassive (310^8 solar masses) central object. This object emits two small but conspicuous jets in the radio wavelength. Three supernovae have been reported so far.

Probably because of its greater distance, M84 is not particularly well studied. Most recent research interest has been concerned with the study of the supernovae rather than with the AGN.

M85

M85 is an early-type lenticular galaxy in Coma Berenices, the northernmost member of the Virgo cluster. It has a distance of approximately 60 million light-years and is very similar to M84 in many respects: it also has an old yellow population and a fairly luminous disk.

The most interesting aspect of M85 is its x-ray properties. Unlike most of the other early-type Virgo galaxies, it is very faint in x-rays and its spectrum seems to consist of two parts—a hard (i.e. more energetic) part possibly caused by a population of evolved stellar sources such as low-mass x-ray binaries, and a soft (i.e. less energetic) part that may be due to hot interstellar medium. This is unusual because the x-ray spectrum of a galaxy like this is normally dominated by emission from the interstellar medium.

M86

M86 is a lenticular or elliptical (classification is not entirely clear) galaxy in Virgo, one of the largest in the Virgo cluster. It has a conspicuous system of faint globular clusters and a very small dwarf companion. Since it lies at the heart of the Virgo cluster, its light is actually blue-shifted with respect to us (i.e. the galaxy is moving towards us), probably due to infall into the Virgo group from the far side.

M86 has a faint plume of x-ray emission extending out from the optical shape of the galaxy. It has been speculated that this is due to ram pressure of the intercluster medium which is stripping the galaxy of its gas. In addition to the plume, a faint optical distortion has been detected, probably due to star formation caused by cooling in the hot gas that is being stripped. This has caused a great amount of interest in the galaxy since it offers a rare chance to observe star formation in a cooling flow environment. M86 forms a small group together with M84.

M87: The Massive Galaxy

Messier 87 (NGC 4486) is a giant elliptical galaxy which dominates the core of the nearby VIRGO CLUSTER of galaxies at a distance of about 16 Mpc from the Sun. It is the archetypal example of the class of brightest cluster galaxies which dominate the centers of many rich concentrated clusters and, with a total visual magnitude of about 9.6, it is about 4 times brighter than our own Milky Way Galaxy would appear at the same distance. In addition to a striking visual appearance (see figure 1), it is also famous as the host galaxy of the bright radio source VIRGO A and the spectacular jet associated with its active galactic nucleus (see M87: THE NUCLEUS AND JET). M87 is in fact not the most luminous galaxy in the Virgo cluster; the bright elliptical Messier 49 (NGC 4472) located some 4.5° away is ∼0.2 magnitudes (22%) brighter. However, M87 is the centrally dominant galaxy, and it is this privileged position which has made it the subject of many different studies.

Like most ELLIPTICAL GALAXIES, M87 exhibits a smooth distribution of light decreasing rapidly away from the center. Near the middle it appears almost round, but on very deep images it looks noticeably flattened with an apparent axial ratio of about 0.6. The intrinsic shapes of elliptical galaxies are difficult to determine and, unlike spiral galaxies, most do not contain extended disks of rotationally supported cold hydrogen gas with which to determine their masses. From an observational point of view, therefore, the question of whether elliptical galaxies are surrounded by massive halos of DARK MATTER like their disk galaxy counterparts is still open to debate (see also DARK MATTER IN GALAXIES).

There are three main methods which have been used to constrain the extended mass distributions in elliptical galaxies such as M87. These are (i) analysis of the mean streaming motions and velocity dispersions of the integrated starlight, (ii) the use of globular clusters as tracers of the gravitational potential and (iii) the analysis of temperature and brightness profiles for hot x-ray emitting gas surounding the galaxy.

Stellar kinematics

Spectroscopic studies of the integrated light from galaxies can yield important information on the motions of stars within the galaxy, from analysis of the positions, widths and shapes of absorption features in the spectra. For nearly spherical galaxies such as M87, the interpretation of these kinematical data in terms of a dynamical model is usually carried out within the framework of the spherically symmetric Jeans equation:

$$\frac{1}{\rho}\frac{\mathrm{d}(\rho\sigma_\mathrm{r}^2)}{\mathrm{d}r} + 2\frac{\beta\sigma_\mathrm{r}^2}{r} = -\frac{GM(r)}{r^2}$$

where $\rho(r)$ is the three-dimensional density of stars at a distance r from the centre of the galaxy, $\sigma_\mathrm{r}(r)$ is the root mean square random velocity (known as the velocity dispersion) in the radial direction, $\beta(r) = 1 - \sigma_\mathrm{t}^2/\sigma_\mathrm{r}^2$ is the velocity anisotropy which measures the relative importance of radial and tangential random motions and $M(r)$ is the total (luminous and dark) mass enclosed within radius r. Unfortunately this problem is underdetermined, given the number of observable properties, and some assumptions need to be made. The simplest of these is to assume that the random motions at any point within the galaxy are isotropic, when $\beta = 0$. Early observations of the core of M87 revealed a velocity dispersion profile which rose toward the center, a feature that was initially attributed to the presence of a massive BLACK HOLE. However, it was soon demonstrated that models without a central point mass were equally acceptable if the velocity dispersions became radially elongated towards the center. In fact, the most recent stellar kinematical data reveal that the velocity dispersion increases only slowly within the inner few arcseconds of M87. To reconcile these observations with the $3 \times 10^9 M_\odot$ black hole inferred from Hubble Space Telescope studies of ionized gas within 1″ of the center requires that the stellar orbits in this region are in fact nearly circular. This has been interpreted as evidence that the center of M87 once contained a binary black hole which preferentially depletes stars on low-angular-momentum orbits via three-body encounters, leaving a largely tangential velocity dispersion.

Outside the core, the velocity dispersion continues to fall steadily with increasing radial distance. However, the stellar absorption-line spectra are very hard to observe

Figure 1. The massive galaxy M87. The swarm of pointlike objects surrounding the galaxy are its rich population of globular clusters. **This figure is reproduced as Color Plate 36.**

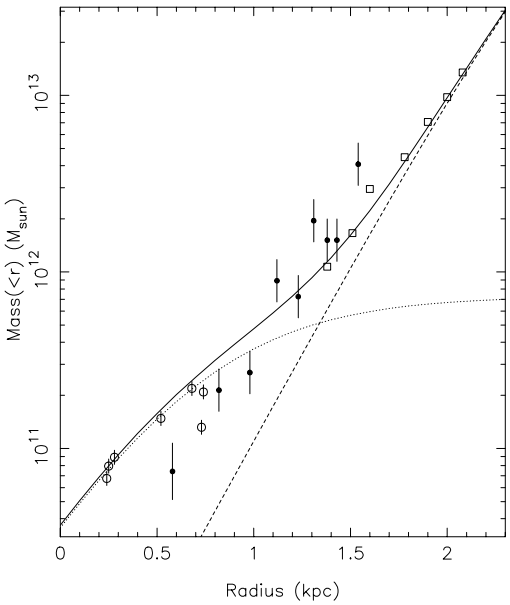

Figure 2. Enclosed mass as a function of radius from the center of M87. Open circles show the estimates from integrated light studies, filled circles from the globular clusters and open squares from the hot x-ray gas. The dotted curve shows a constant M/L model for the mass distribution due to the stellar halo. The dashed line shows a model fit to the extended dark halo whose density profile has been derived from cosmological N-body simulations. The total mass profile is shown by the solid curve.

with useful signal-to-noise beyond $r \sim 2'$ (10 kpc for a Virgo distance of 16 Mpc), even though the integrated light profile can be followed to beyond 100 kpc. The best estimate of the total stellar mass in M87 is $M \sim 4 \times 10^{11} M_\odot$ within 10 kpc of the center.

A useful measure of the presence of dark matter in galaxies is the 'mass-to-light' (M/L) ratio between the luminosity due to stars (at some particular wavelength) and the inferred mass. For M87 the V-band mass-to-light ratio derived from integrated light studies is $M/L \sim 10$ times that of the Sun. This is close to the upper end of the range of M/L values seen in other elliptical galaxies; extrapolating out to the limits of the stellar halo assuming a constant M/L ratio (i.e. that the mass in the halo traces the starlight) would imply a total mass for the M87 galaxy of $M \sim 9 \times 10^{11} M_\odot$ (figure 2). While the central black hole has a mass which is clearly negligible on these scales, it can still affect the global structure of the galaxy via the scattering and redistribution of stellar orbits on rare passages close to the galaxy nucleus.

Globular clusters

At radii beyond about 10 kpc, there are two independent methods to constrain the global mass distribution of M87. The first uses kinematical studies of the large population of GLOBULAR CLUSTERS which surrounds M87 (see figure 1) as test particles to probe the associated gravitational potential. Globular clusters are compact star clusters of $\sim 10^5$ stars which are found ubiquitously in all types of galaxy, but M87 is atypical in having an unusually large population of more than 10 000 clusters. Although their combined masses contribute only a few per cent of the total mass of the halo, because of their relatively bright magnitudes (more than 50% of the M87 clusters have an apparent magnitude brighter than $m_v \sim 23.5$) their radial velocities can be obtained using large ground-based telescopes. Spectroscopic studies have now been made of more than 200 clusters around M87. The most striking result of these measurements is that the velocity dispersion of the globular clusters *increases* with radius. Dynamical analyses of the kinematics of the globular cluster system can be made using simple projected mass estimators or using the Jeans equation. Both of these methods indicate that M87 is surrounded by an extended dark halo with an enclosed mass which increases approximately as $M(< r) \sim r^{1.7}$. The inferred mass-to-light ratio in solar units ranges from $M/L \sim 10$ at $r = 10$ kpc to $M/L \sim 50$ at $r = 30$ kpc.

X-ray gas

Very extended x-ray emission from hot $T \sim 10^7$ K gas around M87 has been detected with the Position Sensitive Proportional Counter (PSPC) on the ROSAT x-ray satellite. Assuming that the gas is a single-phase medium in hydrostatic equilibrium, and that the underlying gravitational potential is spherically symmetric, the mass distribution in the halo can be obtained uniquely from the run of x-ray surface brightness and temperature with radius. Although the x-ray emission can be detected out to over 300 kpc from the centre of M87, temperature estimates can only be derived for the central 200 kpc. The density and temperature of the gas are related to the mass distribution by

$$M(< r) = -\frac{krT}{G\mu m_p}\left(\frac{\mathrm{d}\log n_e}{\mathrm{d}\log r} + \frac{\mathrm{d}\log T}{\mathrm{d}\log r}\right)$$

where μ is the mean molecular weight of the gas which depends weakly on its chemical composition, n_e is the electron density and the physical constants have their usual meanings. The electron density can be obtained straightforwardly from the x-ray surface brightness distribution. Obtaining the temperature profile is more problematic, but useful limits can be obtained from the energy sensitivity of the PSPC detectors. Single-temperature fits to $T(r)$ indicate that the temperature rises from $kT \sim 1.5$ keV at the center to $kT \sim 4$ keV at 200 kpc. The implied mass distribution is shown in figure 2 and agrees well with that determined from the globular cluster kinematics where they overlap, rising to $M(< r) \sim 10^{13} M_\odot$ within $r = 100$ kpc. Although more recent temperature measurements with the ASCA satellite indicate that the x-ray halo probably contains more than one temperature component, the close agreement between the mass distributions derived from these two methods,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

which rely on different physical assumptions, suggests that the uncertainties are unlikely to be large. Less than 5% of this mass is due to the x-ray emitting gas itself, the remainder residing in a dark matter halo.

Conclusions

M87 is one of the best-studied elliptical galaxies and a good test case for formation theories of brightest cluster galaxies. The rise in the globular cluster velocity dispersion profile and the temperature and density profiles of the x-ray gas both indicate that the mass density is dominated by a dark halo component beyond $r \sim 10$ kpc. Whether such extensive dark matter halos are ubiquitous in elliptical galaxies, particular those outside of rich clusters, is an open question, since the position of M87 at the center of the Virgo cluster makes it difficult to separate the galaxy halo potential from that of the Virgo cluster as a whole. Studies of the global gravitational potential of the Virgo cluster using galaxy radial velocities suggest that the mass distribution continues to rise steeply as shown in figure 2 out to at least $r \sim 1$ Mpc.

M87: The Nucleus and Jet

The giant elliptical galaxy M87 at the center of the VIRGO CLUSTER is one of the clearest and nearest examples of an ACTIVE GALACTIC NUCLEUS (AGN) and therefore has been the subject of a large number of studies over the last three decades (see also M87: THE MASSIVE GALAXY). The discovery by Curtis (1918) of an extended prominence emanating from what appeared to be an otherwise normal ELLIPTICAL GALAXY remained little more than a curiosity until Baade and Minkowski (1954) carried out the first thorough studies of what is now known as the M87 optical jet. The proposal by Blandford and Rees (1974) that jets must play a fundamental role in transporting energy from the nuclear energy source to the extended and distant radio lobes established a sound physical underpinning to further investigations of the AGN phenomenon. The presence of massive BLACK HOLES at the center of galaxies is widely believed to be the common origin of the AGN phenomenon. The black hole model is very appealing because it provides an efficient mechanism that converts gravitational energy, via accretion, into radiation within a very small volume as required by the rapid variability of the large energy output of AGNs (e.g. Blandford 1991).

The AGN standard model comprises a central black hole, with mass in the range $\simeq(10^6$–$10^9)M_\odot$, surrounded by an ACCRETION DISK that releases gravitational energy. The radiation is emitted thermally at the local blackbody temperature and is identified with the 'blue bump', which accounts for the majority of the bolometric luminosity in the AGNs. The disk possesses an active corona, where infrared SYNCHROTRON RADIATION is emitted along with thermal bremsstrahlung x-rays. The host galaxy supplies this disk with gas at a rate that reflects its star formation history and, possibly, its overall mass, thereby accounting for the observed luminosity evolution. Broad emission lines originate homogeneously in small gas clouds of density $\simeq 10^9$ cm^{-3} and size $\simeq 1$ AU in random virial orbits about the central continuum source. Plasma jets are emitted perpendicular to the disk. At larger radii, the material forms an obscuring torus of cold molecular gas. Orientation effects of this torus to the line of sight naturally account for the differences between some of the different classes of AGNs. While this broad picture has been supported and refined by a number of observations, direct evidence for the existence of accretion disks around SUPERMASSIVE BLACK HOLES is sparse and detailed measurements of their physical characteristics are conspicuous by their absence.

The black hole in M87

Ground-based observations of M87 first revealed the presence of a cusplike region in its radial light profile accompanied by a rapid rise in the stellar velocity dispersion and led to the suggestion that it contained a massive black hole (Young *et al* 1978, Sargent *et al* 1978). Stellar dynamical models of elliptical galaxies showed, however, that these velocity dispersion rises did not necessarily imply the presence of a black hole but could instead be a consequence of an anisotropic velocity dispersion tensor in the central 100 pc of a triaxial elliptical potential. Considerable controversy has surrounded this and numerous other attempts to verify the existence of the black hole in M87 and other nearby giant ellipticals using ground-based stellar dynamical studies.

One of the major goals of the HUBBLE SPACE TELESCOPE (HST) has been to establish or refute the existence of black holes in active galaxies by probing the dynamics of AGNs at much smaller radii than can be achieved from the ground. HST emission line imagery of M87 has led to the discovery of a small-scale disk of ionized gas surrounding its nucleus which is oriented approximately perpendicularly to the synchrotron jet. This disk is also observed in both the optical and the UV continuum. Similar gaseous disks have also been found in the nuclei of a number of other massive galaxies, e.g. Cen A. Work by Macchetto and collaborators (1997) using the Faint Object Camera (FOC) on the HST has shown unambiguously for the first time that there is a thin Keplerian disk extending to a distance of at least 1″ or 73 pc from the center. By measuring the rotation curve from 1″ (73 pc) down to 0.″06 (3.5 pc) they could derive a number of key parameters for the disk, notably a central mass concentration of $(3.2 \pm 0.9) \times 10^9 M_\odot$ within a sphere of less than 3.5 pc radius and an inclination of the disk to the line of sight of 41°, and showed that the most likely and simplest explanation for this huge mass is that it is a supermassive black hole.

The extended disk

At distances of 1″–2″, or 73–146 pc, the disk morphology shows a three-arm spiral pattern and at larger distances yet the gaseous structure becomes less and less organized until it appears to connect with an extended (17″ or 1200 pc) system of filaments which show prominent emission notably in Hα. This prompted Sparks and collaborators (1993) to suggest a causal relationship between the extended filaments and the inner disk and propose that the filaments are streamers of gas flowing away from the nucleus, rather than falling into it. To date this scenario has had some supporting evidence from measurements of blueshifted broad absorption lines in the nuclear spectrum, which can be interpreted as implying both turbulence and an outflow of material away from the nucleus. A possible model to explain these lines and the observed emission line filaments is that they are the result of a bi-directional wind generated in the accretion disk; this wind also removes angular momentum from the disk to allow accretion through the disk onto the black hole.

The jet

Emanating from the nucleus is the jet which shows considerable structure, with a sequence of bright features reaching ∼25 arcsec from the galaxy center. A counterjet is not detected either at optical or at radio wavelengths, although imaging polarization measurements of the south-eastern radio lobe (Sparks *et al* 1991) found a

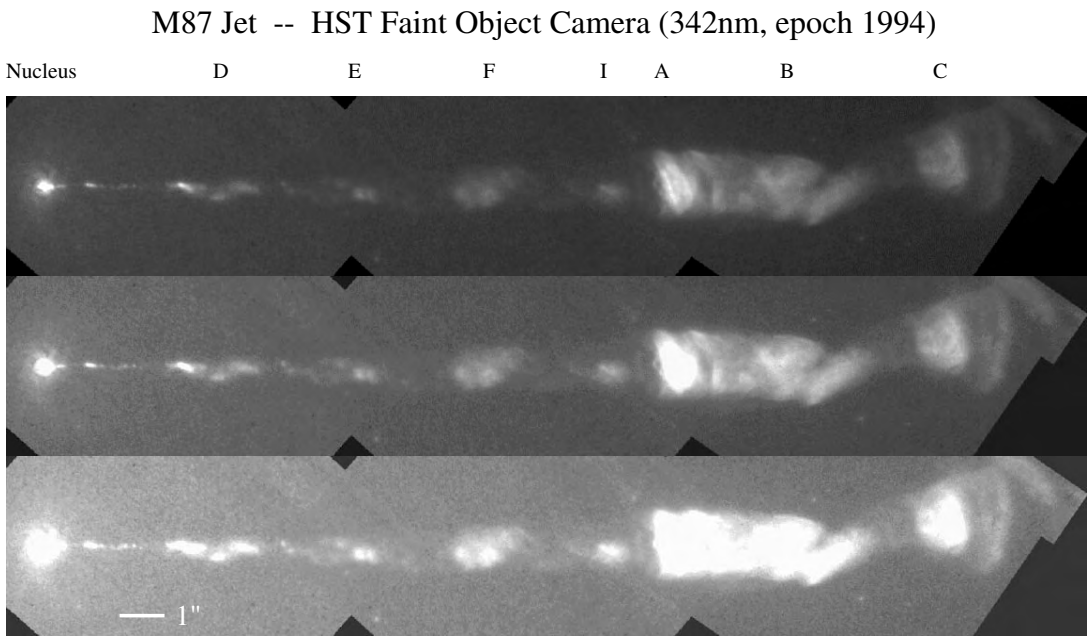

Figure 1. HST FOC image of the jet observed at wavelength 342 nm in 1994 with 0.03 arcsec resolution. Each image is a mosaic of three different FOC pointings. The three panels show the same image at different contrast settings. Knots are labeled with usual letter designations.

polarized counterlobe, thus providing evidence for the existence of an invisible counterjet. Within observational limitations it has been recognized that the detailed morphology of the jet is similar in the radio and optical bands and consistent with those in the infrared and x-ray bands. VLBI mapping shows the nucleus to have an asymmetric, complex 'core–jet' structure extending ∼0.2 arcsec and subluminal motion with velocity $\sim 0.3c$ has been detected for a bright component in the nuclear jet. The jet is highly polarized and it is generally accepted that it emits through the synchrotron process. A fundamental question posed by the observations of the jet is where the synchrotron-radiating electrons are accelerated. Are they accelerated in the nucleus and transported to the sites of the emission? The very short lifetimes of the electrons emitting in the optical to x-ray regions in a uniformly filled jet compared with the light travel time from the nucleus to the end of the observed jet appears to rule this out and suggest that *in situ* particle reacceleration occurs in locations along the jet.

High-resolution images of the jet taken in the UV with the FOC reveal a wealth of details. Figure 1 shows the entire jet as seen by the FOC at 0.03 arcsec resolution (∼2.4 pc). Many structural details of the classical knots are readily apparent, as are many new compact structures. The first 200 pc of the jet—roughly the region between the nucleus and knot D—appears as a narrow chain of numerous bright, unresolved knots. The opening angle of the jet as defined by this chain of features is extremely narrow, less than about 1°, whereas a value near 6.5° is apparent for the rest of the jet beyond knot D. There are additional compact features between knots D and E, as well as bright, slightly resolved condensations (scale ∼0.1 arcsec) throughout the knots D, E, F and I of the 'inner' jet.

The FOC images also reveal many fine structures within the knots that are apparent for the first time. Knot A, in particular, is the brightest knot in the jet and is thought to represent a shock in flow. The eastern edge of knot A also shows several faint structures which are symmetric about the jet axis and which must be related to the impending 'shock' in the bulk flow at knot A. There is a faint 'bar' of emission centered on the jet axis and very nearly perpendicular to it; this is a shock in the high-speed flow at the jet center. There are also faint 'fans' of emission that start at the jet edge adjacent to the bar and then trail inwards towards the jet axis and a faint loop or 'cap' of emission precisely on the jet axis before the brightest region of knot A. These features are all related to shocking of the bulk flow at knot A, and represent conical sheets seen in projection, and are similar to those predicted in numerical models.

A comparison of the FOC and VLA (VERY LARGE ARRAY) images taken at nearly the same epoch in 1994 reveals systematic differences all along the jet. In the radio image, there is faint diffuse emission which appears to fill the jet from the nucleus to knot A and defines the edges of a cone with an opening angle of about 6.5°. While traces of interknot emission are also present in the FOC image, it is much fainter relative to the knot emission. In addition, the optical emission in the knots is more condensed along the jet axis. There are other detailed differences in knot

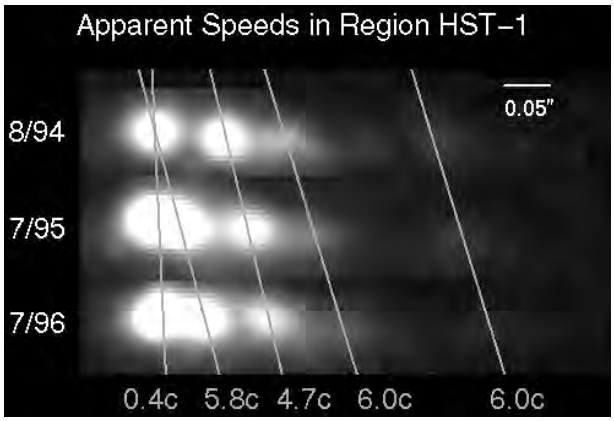

Figure 2. Sequence of HST FOC images of jet region HST-1 which is located about 1 arcsec from the nucleus. The images are observed at $\lambda = 342$ nm at epochs August 1994, July 1995, and July 1996. The slanting lines connect features between epochs, with apparent speeds given in units in c, the velocity of light.

structure, especially in and around knot E. The optical images show a bright pair of condensations in knot E, but these are only a relatively faint region in the radio image. Similarly there is a pair of unresolved features in the optical image between knots D and E, which again are not apparent in the radio image.

Polarimetry

High levels of polarization are a key characteristic of synchrotron radiation. POLARIMETRY provides clues to the direction of the magnetic field within the jet and hence is one of the most important diagnostics for deciphering its structure. The radio polarization has been well studied and it was found that the field is primarily parallel to the jet axis, except in the bright transverse features in knots A and C, where the B field runs along the transverse feature (i.e. normal to the jet axis). The parallel field in most of the jet can be understood as arising from shearing of a random field, while the perpendicular fields could arise from compression at shocks.

Optical polarimetry is especially interesting, because it can potentially tell us about the three-dimensional structure of the jet (Perlman *et al* 1999). The optical emission is more concentrated on the jet axis, and hence it provides an opportunity to obtain information about the magnetic structure at different depths within the jet. We observed typical fractional polarizations that are in the range from 30% to 50% and are comparable with those in the radio band. The magnetic field is generally aligned along the jet, except in the bright transverse features in knots A and C, and at the upstream ends of HST-1 and knot D, where the field runs perpendicular to the jet axis. There is evidence for radio–optical polarization differences in knot E and in the knot A 'bar' region which are attributed to radial structure in the jet.

Proper motion

A 5 yr search for secular variations in the jet—including structural changes, flux variations, proper motions and changes in polarization—is under way (Biretta *et al* 1999). This work can give important clues to the velocity field within jets, about which very little is known from direct observation. Monitoring with the VLA at radio frequencies has detected motion in much of the jet with apparent speeds averaging near $0.5c$. The very fastest regions of these wavelengths are in knot D and appear to move outward with speeds near $2.5c$. At optical wavelengths one of the most active regions in the jet is the complex of compact knots about $1''$ (73 pc) from the nucleus designated HST-1. Figure 2 shows a sequence of FOC images from 1994 to 1996. The complex contains a bright eastern component which moves outward slowly ($0.4c$) and which appears to emit bright compact knots at speeds in the range from $4c$ to $6c$. The emitted components rise and fade within 1 yr. The eastern component is a slow-moving disturbance or shock in the flow, while the fast components are representative of the jet fluid speed. Similar speeds are seen in knot D (figure 3), with measured outward velocities in the range from $2.6c$ to $5.0c$, and there is rapid fading (half-life <1 yr) in features FOC3 and FOC4, which are located just east of knot D. The large speeds have a number of interesting implications within the context of the standard relativistic beaming model. The largest speeds give the strongest constraints, and the observed speed of up to $6c$ implies motion with typical Lorentz factors $\theta = 18^\circ$ and $\gamma = 12$, which are quite consistent with those predicted by the unified models for FR-I sources.

Conclusions

The study of the jet and nuclear regions of M87 has provided an unprecedented laboratory to test many of the recurrent theories of AGN and will continue to give us important clues for the understanding of the relevant physical processes.

M88

M88 is a spiral galaxy in Coma Berenices at a distance of between 12 and 17 Mpc. It is also a member of the Virgo cluster. The galaxy falls into the category of flocculent spirals, which means that it has a stochastic spiral structure in its stellar disk with a faint two-arm structure in the infrared indicating a possible underlying density wave. Its most interesting feature is the chemically decoupled nucleus, i.e. the galaxy has a chemically distinct, metal-rich nucleus of a distinctly different age from the bulge. Additionally, the observation of secondary star-formation bursts may indicate the existence of several more chemically distinct stellar subsystems. The origin of this phenomenon is not known.

In 1999 a supernova was observed in M88.

M89

M89 is an elliptical galaxy in Virgo at a distance of about 60 million light-years. It is a member of the Virgo cluster.

In the optical, M89 does not show any unusual features but in the radio wavelengths it has a faint enveloping structure as well as a jetlike extension reaching about 10′ out from the center. The radio core is of low luminosity but variable. It also emits strongly in the UV—UV light is usually associated with direct non-thermal radiation or dust heated by stars, but both of these are absent from the optical data. So far, no theory has been proposed that could explain all of these features, but the Hubble Space Telescope recently discovered a very small AGN (active galactic nucleus) at the center of this galaxy. It is thought to be a modest accretion event onto a black hole and represents the faintest AGN known so far.

M9

M9 is a globular cluster in the constellation of Ophiuchus (3 degrees south and 2 degrees east from η Ophiuchi), only 5500 light years from the Galactic Center. It has a visual brightness of 7.3 mag which is partly because of its great distance from the Sun (26 000 light-years) but also because it lies at the edge of a dark nebula and is hence dimmed by dust to the north and west. The cluster is slightly elliptical in outline and has a diameter of 49 light-years.

Walter Baade investigated M9 for variable stars and found just 13, 10 of which have periods around 2.4 days.

M90

M90 is one of the larger spirals in the Virgo cluster but it has little mass. It also has one of the largest velocities of approach of all the Messier objects and may possibly be in the process of escaping from the Virgo cluster. Its spiral arms are tightly wound and smooth but, unusually for a spiral, there is no ongoing star formation in the arms but only in the inner disk region. The galaxy may currently be evolving into a state similar to M64.

M91

M91 in Coma Berenices was long regarded as one of the 'missing' Messier objects, since nothing nebulous could be seen near its listed position. It was even suggested that Messier had really seen a comet at this position in March 1781 but not recognized its true nature. In 1969 a Texan amateur, William C Williams, gave what is now accepted as the probable answer: Messier originally measured the position of this object through his telescope by reference to M89, but when he came to write up his observations he mistakenly applied the correction to the coordinates of M58, another galaxy in this area. The resulting position coincides with that of NGC 4548, a tenth-magnitude barred spiral which would have been within reach of Messier's telescope. If M91 is indeed the same as NGC 4548, it is a member of the Virgo cluster, but is fairly unremarkable visually in small amateur instruments.

M92

M92 is an exceptionally ancient globular cluster in Hercules which would be better known if it were not overshadowed by M13. It was discovered by Johann Bode in 1777 and rediscovered in 1781 by Messier, although since it is bright enough to be just visible to the naked eye under ideal conditions it is surprising that it was not recognized earlier. As in most globulars, almost all the known variables in M92 are short-period pulsating variables of the RR Lyrae type, although in this case there is also a rarity: an eclipsing binary of W Ursae Majoris type. A study of M92 by H Arp, W Baum and A Sandage found that the most luminous members of the cluster are red giants with absolute magnitudes of around −3. Visually, in small instruments, M92 has a very condensed center with a surrounding coma like the head of a comet. Analysis of results from the Hipparcos satellite gives a distance for M92 of about 29 000 light-years, slightly farther than M13, and an estimated age of 14 billion years, making it the oldest globular known.

M93

M93 is an open cluster situated almost exactly on the galactic equator in Puppis. Of sixth magnitude, it is at the limit of naked-eye visibility and is easily detectable with binoculars, near third-magnitude Xi Puppis. It is elongated, and through small telescopes appears shaped somewhat like the tip of a knife, although Admiral Smyth called it starfish-shaped. M93 was discovered by Messier in March 1781, and described by him as a 'cluster of small [i.e. faint] stars without nebulosity'. Modern measurements identify the brightest stars as blue giants of eighth magnitude, among a total of some 60 stars covering a diameter of about 18 arc minutes. However, it is difficult to determine how far the outer reaches really do extend; published diameters for the cluster range from only 8 arc minutes (Messier's own estimate) up to 24 arc minutes. Modern distance determinations put the cluster at 3600 light-years from us, giving it a true diameter of about 20 light-years, and its age is some 300 million years.

M94

M94 is a spiral galaxy in Canes Venatici, lying just north of a line between Alpha and Beta Canum Venaticorum. The galaxy is presented almost face-on to us and in small telescopes appears almost perfectly rounded with a bright nucleus; Admiral Smyth understandably called it 'comet-like'. It is classified as midway between type Sa and Sb, meaning that its arms are quite tightly wound. Small telescopes reveal traces of its spiral arms,which contain many patchy dust clouds in their inner regions. Ultra-violet observations have revealed a ring of star formation over 7000 light-years in diameter around this galaxy's core. Long-exposure photographs with large instruments reveal an outer ring of light as well, both rings providing evidence for past activity in the galaxy. M94 was discovered in March 1781 by Mechain, as were all the subsequent objects in Messier's catalog. M94 is around 15 million light years away.

M95

M95 is a barred spiral galaxy in Leo, under the body of the lion about a third of the way from Alpha to Beta Leonis. It was discovered in March 1781 by Mechain but at tenth magnitude is faint and difficult for small telescopes. M95 is presented almost face-on to us, displaying a central bar and tightly wrapped spiral arms that together create the shape of a Greek theta. M95 forms a pair with nearby M96, usually regarded as lying around 25 million light-years away, although observations with the Hubble Space Telescope in 1995 suggest a distance about 50% greater.

M96

M96 is a spiral galaxy in Leo, lying about two-thirds of a degree to the east of M95. Like that galaxy, it was discovered in March 1781 by Mechain and was then checked by Messier before inclusion in his catalog. Visually, it appears rounded with a bright center and traces of spiral arms; it is classified as type Sa. A supernova of type Ia erupted within it in 1998. M96 lies at a similar distance to M95, although estimates of the distances are discrepant. A figure of around 25 million light-years has usually been adopted, but observations of Cepheid variables in M96 with the Hubble Space Telescope have yielded a distance closer to 40 million light-years. Whatever the true distance, these galaxies, and M105 to the north, are seemingly part of a small cluster, the Leo Galaxy Group, that also includes M65 and M66.

M97

M97 is a planetary nebula in Ursa Major, lying just south of the bowl of the Big Dipper, 2.25 degrees from Beta Ursae Majoris. This nebula was discovered in February 1781 by Mechain, who noted it was difficult to see; modern observers estimate it as either tenth or eleventh magnitude, placing it among the faintest objects in Messier's catalog. Lord Rosse in 1848 named it the OWL NEBULA because its rounded outline with two dark patches gave the impression of an owl's face. Rosse claimed at the time that a star was visible in each cavity, like a pair of eyes, but the fainter of these subsequently vanished; perhaps it was not a true star at all but a brighter knot of nebulosity. There is, though, a central star, listed variously as fourteenth or sixteenth magnitude, which is the source of the nebula's gas. Visually through small telescopes the Owl appears as a pale, grey disk larger than Jupiter, although larger instruments (and long-exposure photographs) reveal a greenish colour. As with all planetary nebulae its distance is uncertain, but is probably in the region of 1500 light-years, somewhat more distant than M27 but still among the closest planetaries to us.

M98

M98 is a spiral galaxy in southern Coma Berenices, just 0.5 degrees from the fifth-magnitude star 6 Comae Berenices. It was a Mechain discovery, in March 1781. M98 is a spiral galaxy of intermediate type lying nearly edge-on to us, as a result of which it appears extremely elongated in shape, about four times longer than it is wide. William Herschel in 1783 declared that 'its feeble branches extend above a quarter of a degree', although only large telescopes will show it this big; in amateur instruments its length will be about half as large as Herschel saw it, and the nucleus appears star-like. Although lying in Coma, M98 is actually a member of the Virgo Cluster. One surprising aspect is that it shows not a redshift but a blueshift, indicating it is moving towards us at a relative speed of 140 km s^{-1}. In fact, it is not the only Virgo cluster member to show a blueshift, nor does it have the largest value; rather,these discordant figures demonstrate that there is a wide range of motions among the individual members of large clusters such as that in Virgo.

M99

M99 is a spiral galaxy in Coma Berenices. It was another Mechain discovery in March 1781, on the opposite side of the fifth-magnitude star 6 Comae Berenices from M98, but the two galaxies are of quite different appearance. Whereas M98 is edge-on to us, M99 is turned almost face-on so that it appears rounded in small instruments. It is classified as type Sc. Unusually, it seems to possess three spiral arms (a symmetrical two is the most common arrangement), although these will be visible only in larger apertures or on long-exposure photographs. They were first seen by Lord Rosse in 1848, making this the second galaxy in which spiral structure was definitely detected (M51 was the first), although of course at that time the true nature of galaxies was not recognized. M99 has been the site of three known supernovae, in 1967, 1972 and 1986. In contrast with M98, which shows a small blueshift, M99 has one of the largest redshifts of any galaxy in the Virgo Cluster, 2400 km s^{-1}.

Mach, Ernst (1838–1916)

Moravian/Austrian physicist, scientist/philosopher, the basis of whose natural philosophy was that all knowledge is a matter of experiments, indeed sensations, so that 'laws of nature' are summaries of experience provided by fallible senses. EINSTEIN, who had been taught by Mach, was very influenced by this perspective and developed the theory of relativity, expressing much the same thing by incorporating the speed of light into concepts of simultaneity, etc. *Mach's Principle* is a philosophical statement that in some way the properties of a body are influenced by the properties of all the other bodies of the universe. This is not easy to interpret scientifically, but the principle influenced Einstein's concept of space-time. Contrary to Einstein's belief that he had produced the theory of general relativity in conformance with this principle, WILLEM DE SITTER found solutions to Einstein's field equations in the absence of matter, i.e. no matter exists other than the test body, but it does have inertia. Mach also worked on acoustics, and the ratio of a body's speed to the speed of sound is known as the *Mach number*.

Maclaurin, Colin (1698–1746)

Born in Kilmodan, Argyllshire, Scotland, became professor of mathematics at the University of Edinburgh and worked on the theory of tides, the impact of bodies, and in 1742 published his *Treatise of Fluxions*, the first systematic exposition of NEWTON's methods. Its influence was negative in that it prolonged the currency of Newton's geometric approach to calculus rather than the algebraic analysis developed on the continent. In the book, he used the special case of Taylor's series now named the *Maclaurin series*.

Maffei 1 and 2

Two relatively nearby galaxies which lie so close to the plane of the Milky Way that they are almost completely obscured by interstellar dust. They were discovered in 1968 as a result of infrared observations conducted by the Italian astronomer, Paulo Maffei. Maffei I appears to be an elliptical galaxy, located at a distance of about 330 000 light-years. Maffei 2 is a spiral galaxy that lies at a distance of some 15 million light-years.

Magellan

Highly successful NASA Venus orbiter, launched from Space Shuttle Atlantis in May 1989. Arrived at Venus in August 1990. Used synthetic aperture radar to map 98% of the surface of Venus at 120–300 m resolution and provided global altimetry data. Revealed more than 1000 impact craters and 1100 volcanic features. Also discovered sinuous valleys, and unique geological structures known as coronae and arachnoids. Precision radio tracking of the spacecraft measured Venus' gravitational field. Entered the planet's atmosphere in October 1994.

Magellan, Ferdinand (1480?–1521)

Portuguese explorer, whose crew brought back from his voyages into the southern hemisphere news of the existence of what became known as the *Magellanic clouds*. At first, they were conceived as two fragments of the Milky Way that had somehow come loose, but now are known to be the two nearest galaxies to our own. The Magellan spacecraft to Venus commemorates his explorations.

Magellanic Clouds: Interstellar Phenomena

The LARGE and SMALL MAGELLANIC CLOUDS are two naked-eye IRREGULAR GALAXIES in the southern sky. Extending over $\sim 7^\circ \times 7^\circ$, the Large Magellanic Cloud has a prominent stellar bar superposed on a disk, which is tilted by about 40° with respect to the sky. The Small Magellanic Cloud, $\sim 4^\circ \times 3^\circ$, has a bar-like structure, with its long axis stretched along the line of sight. The Large and Small Magellanic Clouds are at distances of 50 kpc and 60 kpc, respectively, and are believed to be satellite galaxies of our MILKY WAY. Their masses, $2 \times 10^{10} M_\odot$ and $2 \times 10^9 M_\odot$, are much smaller than the mass of the Milky Way, a few times $10^{11}\ M_\odot$.

The Magellanic Clouds are close enough to each other and close enough to the Milky Way that tidal interactions have significantly altered the distribution of their masses. Tidal interactions are responsible for the formation of the stellar bar in the Large Magellanic Cloud as well as the elongated geometry of the Small Magellanic Cloud. A large-scale neutral hydrogen (H I) map of the Magellanic Clouds (figure 1) shows that tidal interactions have produced not only the Magellanic Bridge between the two galaxies, but also the MAGELLANIC STREAM trailing behind the Small Magellanic Cloud and a Leading Arm in the opposite direction. The Magellanic Clouds cannot be considered as independent galaxies; they form a 'Magellanic System'.

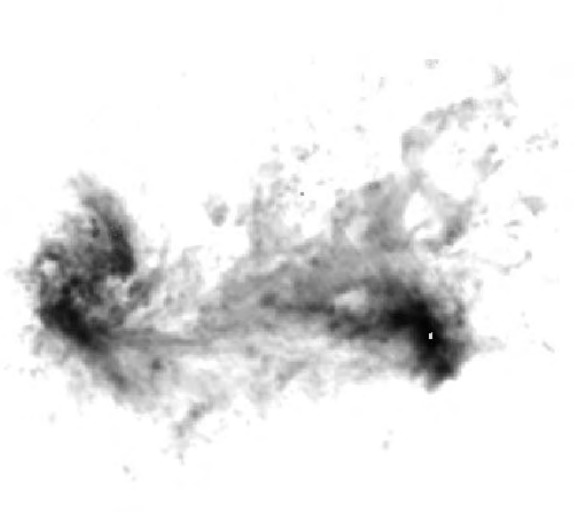

Figure 1. A neutral hydrogen view of the Large Magellanic Cloud (on the left) and the Small Magellanic Cloud (on the right). The gas connecting the two galaxies forms the Magellanic Bridge. The start of the Magellanic Stream can be seen above the Small Magnellanic Cloud. This image was obtained with the Parkes multibeam receiver of the Australia Telescope. Image courtesy of R Haynes *et al*.

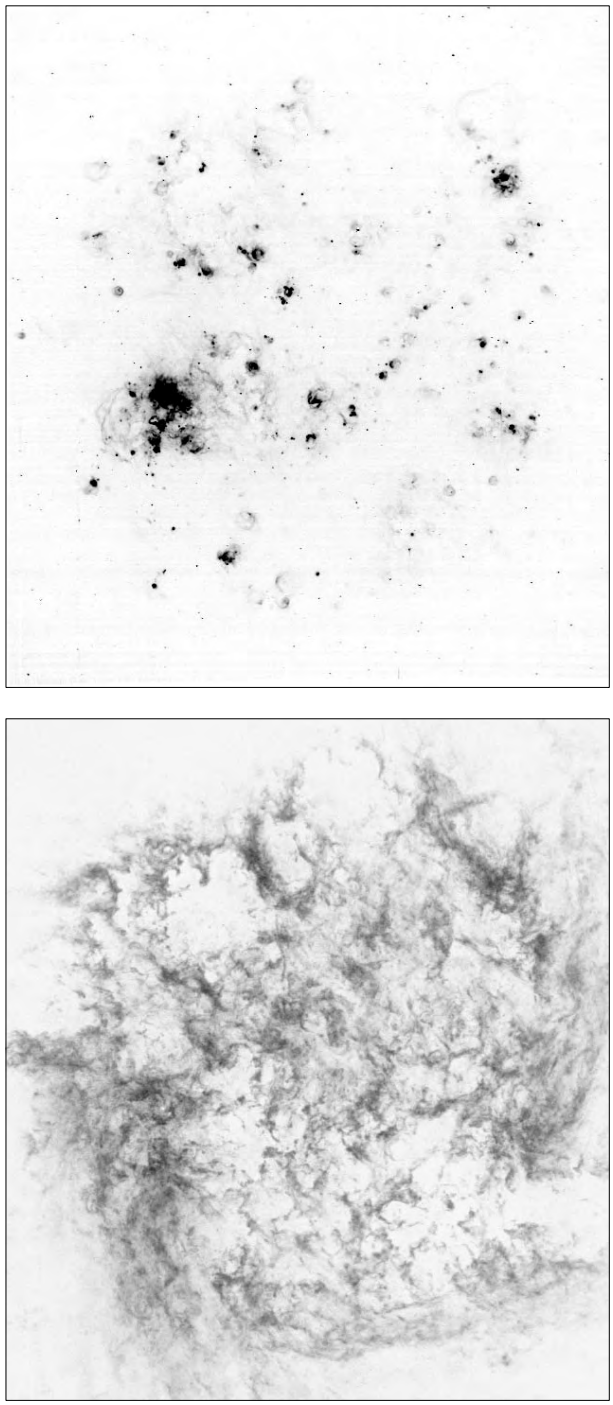

Figure 2. (Top) Hα image of the Large Magellanic Cloud showing the 10^4 K ionized interstellar gas. The main body of the Large Magellanic Cloud is $7^\circ \times 7^\circ$. The brightest nebula is the giant H II region 30 Doradus. Shells of various sizes are clearly seen. (Bottom) H I 21 cm line image of the Large Magellanic Cloud with the same field of view. The Hα image was taken with M Bessell's CCD camera at Siding Spring Observatory. The H I map was obtained with the Australia Telescope Compact Array and the Parkes 64 m Radio Telesope. Figure 3. (Top) Hα image of a portion of the Large Magellanic Cloud centered on the 30 Doradus complex. (Bottom) Soft x-ray image of the same region in the 0.1–2.0 keV band. The field of view is $140' \times 110'$. Diffuse x-ray emission is clearly detected in supernova remants, some superbubbles, the giant H II region 30 Dor and two supergiant shells. The Hα image was taken with the Curtis Schmidt Telescope at Cerro Tololo Inter-American Observatory. The x-ray image was a mosaic of observations made with the High Resolution Imager on board the ROSAT x-ray satellite (Röentgen Satellite).

Interstellar shells

The Magellanic Clouds are active in STAR FORMATION and contain large numbers of massive stars. Massive stars ionize the ambient interstellar medium via their ultraviolet radiation and dynamically interact with the ambient medium via fast stellar winds and supernova blasts. The dynamical interactions sweep the ambient interstellar gas into dense shells that are best seen in Hα images (figure 2). The wide variety of interstellar shells in the Magellanic Clouds are formed by the following mechanisms. (1) Single massive stars blow 'bubbles' during their lifetime and form SUPERNOVA REMNANTS eventually. These shells usually have sizes of a few to a few tens of parsecs. (2) Massive stars in an OB ASSOCIATION collectively produce 'superbubbles' in the interstellar medium, and their sizes are a few tens of to a couple of hundred parsecs. (3) When multiple generations of star formation have taken place close to one another, an interstellar 'hole' or a 'supergiant shell' with a diameter as large as 1000 pc may form.

The Large Magellanic Cloud has ∼40 known supernova remnants, including the young remnant of SN 1987A, ∼20 superbubbles around OB associations and 10 supergiant shells. The Small Magellanic Cloud has fewer interstellar shells; for example, it has ∼15 known supernova remnants, and only one supergiant shell has been identified. The Magellanic Clouds are the only galaxies where superbubbles and supergiant shells can be studied comprehensively, as both the physical conditions of the shells and their underlying massive stellar content can be resolved and studied in great detail (see also MAGELLANIC CLOUDS: STAR POPULATIONS).

Multiphase interstellar medium

The interaction between massive stars and the interstellar medium produces shock-heated gas at a few 10^6 K. The mixture of hot ionized gas and cooler ionized and neutral gas forms a multiple-phase structure within the interstellar medium. The Magellanic Clouds provide ideal laboratories to study the multiphase interstellar medium because of their proximity, low extinction and small inclination angle.

The Hα image and the H I 21 cm line map of the Large Magellanic Cloud show vastly different morphologies (figure 2). The ionized warm gas is distributed near recent star-forming regions, while the neutral atomic gas shows fossil shell structures accumulated from previous epochs of star formation.

The distribution of the hot ionized gas relative to the cooler gas is revealed by comparisons of soft x-ray images with Hα images (figure 3). The distribution of the hot ionized gas has a good correspondence to that of the cooler ionized gas, or star formation regions. Hot ionized gas is present in supernova remnants, the giant H II region 30 Doradus, superbubbles, supergiant shells and the unbounded fields. It is conceivable that the hot ionized gas was initially produced and confined in the central cavities of interstellar shells. The hot gas can be injected into the halo, if a shell is larger than the scale height of the gas disk, e.g. a supergiant shell. The hot gas may escape the shell interior if the ambient medium is inhomogeneous and a breakout occurs. These mechanisms can satisfactorily explain the distribution of the hot ionized gas with respect to the cooler gas.

Most of the mass of the interstellar medium is in the neutral components. The Large and Small Magellanic Clouds have H I masses of $7 \times 10^8 M_\odot$ and $6.5 \times 10^8 M_\odot$, and molecular H_2 masses of $1.4 \times 10^8 M_\odot$ and $3 \times 10^7 M_\odot$, respectively. The molecular H_2 masses may be somewhat uncertain because they are derived from CO observations and the conversion factors from CO to H_2 for the Magellanic Clouds are not well known because of their lower metallicities and higher ultraviolet radiation field.

Magellanic Clouds: Stellar Populations

The Magellanic Clouds (figure 1) have long been seen as the prototypical young STELLAR POPULATION. The presence of young GLOBULAR CLUSTERS in the Clouds spoke to southern hemisphere observers of the opportunity to study close up processes which have not occurred in the Milky Way for a long time. Young globulars are also seen in other gas-rich, highly disturbed environments, such as merging galaxies (Holtzman *et al* 1996; Brodie *et al* 1998).

Figure 1. The Large and Small Magellanic Clouds imaged by M Bessell with a 3 in camera mounted on the 16 in telescope at Siding Spring Observatory.

The history of star formation

The Hubble Space Telescope has opened up the main sequence in the Magellanic Clouds for detailed study. The pioneering work of Gallagher *et al* (1996) (see figure 2), followed by Holtzman *et al* (1997), yields a good fit with a three-epoch STAR FORMATION history, an initial burst, middle age and a recent burst of star formation. Sufficient main sequence is exposed by the WFPC2 to show that a power law initial mass function (IMF) is a satisfactory fit with $\mathrm{d}n/\mathrm{d}m = m^{-s}$ and $2 < s < 3$, similar to the closest fit in the solar neighborhood. The upper end of the IMF and its high-mass cutoff has been investigated by Massey (1999).

The recent burst began approximately 3 Gyr ago, which may be compared with the orbital timescale of the LMC, 1.3 Gyr (Gardiner *et al* 1994). Multiple LMC fields have now been studied (Geha *et al* 1998) and broadly similar results are seen in all. The star formation history of the LMC as a whole is being studied by Harris *et al* (1999). Olsen (1999) finds that the star formation history of the inner region of the LMC may be more steady. The situation in the SMC is discussed by Hatzidimitriou (1999).

In its cluster formation history the LMC seems to have experienced a quieter middle age according to Da Costa (1999). However, possibly the middle-aged clusters (Sarajedini 1998) were formed and have simply failed to survive. A catalog of Magellanic Cloud associations is provided by Bica *et al* (1999). Comparing the LMC with IC 1613, van den Bergh (1998) draws a distinction between the cluster and field star formation histories.

The Magellanic Clouds have long been the best laboratory for the study of young STAR CLUSTERS. An update on this work is provided by Grebel *et al* (1999). A natural connection can be made between the young clusters and large molecular clouds which reach 2×10^6 solar masses in the NANTEN CO survey (Fukui *et al* 1999).

Kinematics

Details of the stellar kinematics of the Magellanic Clouds pale before the wealth of detail now available on the kinematics of the gas by Kim *et al* (1998, 1999) from the Australia Telescope Compact Array and from the Parkes telescope (see also Putman *et al* 1998). However, a tracer of the intermediate-age population is provided by the CARBON STARS (Kunkel *et al* 1997), which show a cool rotating disk with a circular velocity of approximately 60 km s^{-1}. The cluster kinematics is discussed by Schommer *et al* (1992) and the cluster also forms a simple disk. The stars are too sparse to provide useful age resolution.

Chemistry

The star formation history of the LMC which we have just described together with the assumptions of the simple model of chemical enrichment predict $Z(t)$, the time evolution of the metallicity, which is in quite satisfactory agreement with observations (Dopita *et al* 1997). The present-day stellar abundances are analyzed for Cepheids by Luck *et al* (1998) and by Smith (1999). Da Costa and Hatzidimitriou (1998) trace the chemical evolution of the SMC and find that the simple model is satisfactory. A detailed chemical evolution model is presented by de Freitas Pacheco (1998). A bursting model by Pagel and Tautvaisiene (1998) fits the data very well. An added complication has been introduced by Da Costa (1999), who notes a radial abundance gradient in the LMC's old star clusters.

Surveys

Recent surveys have enriched our knowledge of the Magellanic Clouds. The principal stellar surveys include the EROS and MACHO MICROLENSING surveys, which have yielded a particularly fine harvest of VARIABLE STARS (Alcock *et al* 1999; Beaulieu *et al* 1999), and the photometric survey of Zaritsky (1999).

Magellanic Stream

The Magellanic Stream (MS), which covers an arc of more than 90° across the sky, is a thin band of neutral hydrogen (H I). It is basically continuous, although there are at least six separate regions within the stream where the particle density is visibly enhanced. One end of the MS appears to be connected with the LARGE and SMALL MAGELLANIC CLOUDS, with the other end trailing away from them (see also MAGELLANIC CLOUDS: INTERSTELLAR PHENOMENA). Even though the MS is very close to our Galaxy, at least as far as extragalactic distances are concerned, the process through which it originated is still widely debated.

While it seems most likely that the MS is the result of gravitational interactions (see GALAXIES: INTERACTIONS AND MERGERS), several viable mechanisms exist which could theoretically produce such a feature. One of the major difficulties in determining the origin of the MS is that the exact distance is not known. Another is that while some theories are capable of explaining certain aspects of the MS, there is no theory that can completely reproduce all observed features. Two proposed mechanisms that have each been studied in detail are *ram-pressure stripping* and *tidal stripping*.

There are observed properties of the MS and its surroundings that support the ram-pressure model. First, the edges of the Large and Small Magellanic Clouds on the opposite side of the stream are well defined, as if they are interacting with a gaseous medium through which they are passing. Also, the end of the MS most distant from the Magellanic Clouds has a RADIAL VELOCITY component 200 kilometers per second different from that of the clouds, while the end apparently connected to the clouds does not show this discrepancy. The radial velocity component for the MS, for the most part, shows a smooth and continuous variance between its two ends, as it should if it were the result of ram-pressure stripping. Finally, it has been proposed that the observed clumpy regions within the stream represent regions of gas that lost varying amounts of ANGULAR MOMENTUM through the stripping process.

On the other hand, computer simulations have been performed to examine the tidal stripping model that bear striking resemblance to observations. This simulated stream shows positional agreement with the observed stream, as well as appropriate values for the total mass and radial velocity profile. One difficulty with this model, however, is that theoretically a second stream which leads the Magellanic Clouds should also be produced, but is not observed. While additional regions of neutral hydrogen have been detected in the vicinity of the Magellanic Clouds, it is unclear that any of these should be interpreted as a leading arm. Another difficulty is that stars as well as gas should be affected by tidal forces, while no obvious stellar component has been detected in the MS.

Magnetars

A magnetar (contraction of 'magnetic star') is a NEUTRON STAR for which the magnetic field energy exceeds all other sources of energy, including rotation. In most cases, this implies a magnetic field strength of approximately 10^{15} G, which would make magnetars the objects with the most intense magnetic fields known. Magnetars were initially proposed to explain the properties of the soft gamma repeaters (SGRs) (Thompson and Duncan, 1995). SGRs are sources of short, repeating, super-Eddington bursts of γ-rays (up to ~100 keV). Three are known to exist in our Galaxy (SGR1900+14, SGR1806–20, and SGR1627–41), and a fourth is apparently in the Large Magellanic Cloud (SGR0525–66). (These designations come from their initially determined positions in right ascension and declination; in some cases, however, subsequent refinements of the positions have taken place. By convention, the designations have not been changed to reflect this.) Their locations and possible associations with supernova remnants suggest that they are neutron stars. The SGRs undergo sporadic periods of bursting activity, punctuated by long quiescent intervals. Occasionally (perhaps every century) they emit very intense giant bursts of γ-radiation up to energies of several MeV, whose intensities at Earth are greater than those of any other cosmic source (Hurley *et al*, 1999). The magnetar model postulates that the energy source for all of these outbursts is an intense magnetic field which stresses the neutron star crust and causes it to crack, exciting Alfvén waves and energizing electrons in the neutron star's magnetosphere. Small cracks explain the frequent, less intense bursts, while global cracking and magnetic field reconnection are responsible for the giant bursts. The SGRs are all quiescent, steady sources of low-energy x-radiation (2–10 keV). In several cases, clear evidence is seen for periodic emission, either of quiescent x-rays, or of the bursting γ-rays. The periods are in the range 5–8 s and, in the magnetar model, are explained by the presence of hot spots on the neutron star surface, with magnetic field dissipation and neutron star crustal stress as the heating source. Experimental evidence for the existence of superstrong magnetic fields comes from observations of the spin-down of the SGRs, deduced from the low-energy x-rays (Kouveliotou *et al*, 1998). The interpretation of these observations is that, similarly to the radio pulsars, the neutron star is losing energy by dipole radiation from its magnetic field.

Magnetic Buoyancy

'Magnetic buoyancy' is a term that is applied to two related, though definitely distinct, phenomena. This article is concerned with magnetic buoyancy as a mechanism for destabilizing atmospheres containing magnetic fields that are in mechanical equilibrium. The term is also applied to the buoyancy of an isolated tube of magnetic field; it is however important to note that this latter phenomenon is not a manifestation of an instability, but rather of a lack of equilibrium. Instability driven by magnetic buoyancy is likely to be an important mechanism in the disruption of any large-scale magnetic field. In particular, it is the most probable cause of the break-up of the Sun's large-scale toroidal field, posited to lie at the base of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE).

The basic instability mechanism

The simplest way of understanding magnetic buoyancy as an instability mechanism is to consider an atmosphere in hydrostatic equilibrium with a unidirectional, horizontal magnetic field that depends only on height, z. The equation of magnetohydrostatic balance is then

$$\frac{\mathrm{d}}{\mathrm{d}z}\left(p+\frac{B^2}{2\mu_0}\right)=-\rho g. \tag{1}$$

Suppose that a small parcel of gas (and magnetic field) is raised slowly, without any bending of the field lines, an infinitesimal distance from a height z to $z+\mathrm{d}z$; denote changes within the gas parcel by 'δ' and changes in the atmosphere external to the parcel by 'd'.

Conservation of mass and magnetic flux of the parcel lead to the relation

$$\frac{\delta B}{B}=\frac{\delta\rho}{\rho}. \tag{2}$$

Conservation of specific entropy of the parcel gives

$$\frac{\delta p}{p}=\gamma\frac{\delta\rho}{\rho} \tag{3}$$

where γ is the ratio of specific heats. Maintaining the total pressure balance between the parcel and its surroundings implies that

$$\delta p+\frac{B\delta B}{\mu_0}=\mathrm{d}p+\frac{B\mathrm{d}B}{\mu_0}. \tag{4}$$

Instability occurs if, on displacement, the parcel is less dense than its surroundings (i.e. $\delta\rho<\mathrm{d}\rho$) and hence continues to rise. Manipulation of equations (2), (3) and (4) leads to the following local criterion for magnetic buoyancy instability:

$$-\frac{B^2}{\mu_0 p}\frac{\mathrm{d}}{\mathrm{d}z}\ln\left(\frac{B}{\rho}\right)>\frac{\mathrm{d}}{\mathrm{d}z}\ln(p\rho^{-\gamma}). \tag{5}$$

The left-hand side represents the potentially destabilizing influence of the magnetic field, fields that decrease with height making the gas top-heavy to some extent; the right-hand side is a measure of the convective stability (or instability) of the atmosphere. From the point of view of magnetic buoyancy instabilities, the interesting case is when the atmosphere is convectively stable (i.e., the right-hand side of inequality (5) is positive), any instability thus being driven by the magnetic field.

Further effects

The instability criterion (5) was derived under the most simplifying assumptions possible—no bending of the field lines, no diffusion and no rotation. In this section we shall consider how the instability mechanism is affected by such considerations, all of which are important in an astrophysical context.

Three-dimensional instability

When fully three-dimensional motions are considered, the change in the instability mechanism is quite subtle. On the one hand, bending of the field lines entails work against magnetic tension; this though becomes arbitrarily small as the wavelength in the direction of the imposed field becomes arbitrarily long. On the other hand—and not so obviously—three-dimensional motions can reduce the work done against magnetic pressure. The basic idea is that instability occurs by the release of gravitational potential energy, this being induced by horizontal variations in the density, and hence, also, in the gas pressure. For the two-dimensional modes considered above, in which the field lines remain straight (so-called interchange modes), gas pressure and magnetic pressure are inextricably linked; it is impossible to do work against gas pressure, necessary for producing density variations, without incurring the penalty of doing work against magnetic pressure. However, this constraint is relaxed by irrotational flows that, though compressible, are essentially solenoidal in the plane perpendicular to the imposed field; such motions can generate density fluctuations without having to do work against magnetic pressure. As a consequence, the local criterion for instability to three-dimensional modes is

$$-\frac{B^2}{\mu_0 p}\frac{\mathrm{d}}{\mathrm{d}z}\ln(B)>\frac{\mathrm{d}}{\mathrm{d}z}\ln(p\rho^{-\gamma}). \tag{6}$$

Thus it is the gradient in B that is now the key destabilizing ingredient, compared to a gradient in B/ρ for interchange modes (cf (5)). For two-dimensional motions in the plane of the field (the 'opposite' case to interchange modes), geometrical constraints lead to a more stringent instability criterion than that given by (6).

The role of diffusion

We have so far considered the instability for ideal (diffusionless) MAGNETOHYDRODYNAMICS. In reality, however, the instability will be influenced by the diffusion of magnetic field and heat, and by viscosity (denoted by η, κ and ν respectively). In the SOLAR INTERIOR the molecular

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

values of the diffusivities satisfy the inequalities $\nu \ll \eta \ll \kappa$. In the absence of rotation, viscosity acts merely as a damping mechanism; we shall therefore concentrate here on the role of η and κ and set $\nu = 0$. For simplicity we shall only consider the instability of interchange modes. The diffusive modification to the instability criterion (5) is given by

$$-\frac{B^2}{\mu_0 p}\frac{\mathrm{d}}{\mathrm{d}z}\ln\left(\frac{B}{\rho}\right) > \frac{1}{\gamma}\frac{\eta}{\kappa}\frac{\mathrm{d}}{\mathrm{d}z}\ln(p\rho^{-\gamma}). \qquad (7)$$

It can be seen clearly how instability is facilitated by small values of η (that help maintain the destabilizing magnetic field gradient) and large values of κ (that act to erode the stabilizing entropy gradient).

Diffusive effects also lead to qualitatively new behavior in the form of oscillatory instabilities (i.e. the growth rate $s = s_r + is_i$ with $s_r > 0$ and $s_i \neq 0$). The criterion for such an instability (again with $\nu = 0$) is given by

$$-\frac{B^2}{\mu_0 p}\left(1-\gamma+\frac{\eta}{\kappa}\right)\frac{\mathrm{d}}{\mathrm{d}z}\ln\left(\frac{B}{\rho}\right) > \frac{\gamma}{g}\eta(\eta+\kappa)\frac{k^6}{k_H^2}+\frac{\mathrm{d}}{\mathrm{d}z}\ln(p\rho^{-\gamma}) \qquad (8)$$

where k_H and k are the horizontal and total wavenumbers. The most interesting feature of (8) is the occurrence of instability, for $\eta/\kappa < \gamma - 1$, with $-\mathrm{d}\ln(B/\rho)/\mathrm{d}z$ *negative*, a situation that at first sight one would imagine to be stable. Unsurprisingly, the mechanism behind the instability is very different to that discussed above. However, it is again instructive to consider a small upward displacement of a tube of magnetic flux. From the analysis leading to (5) it follows that if $-\mathrm{d}\ln(B/\rho)/\mathrm{d}z < 0$ then a displaced parcel will be denser than its surroundings and will fall. The crucial element though is that the raised parcel may be hotter than its surroundings; thermal diffusion will then allow the passage of heat from parcel to surroundings, with the possibility that when the tube returns to its initial height it is cooler, and hence denser, than it was originally. If this is the case, it will thus 'overshoot' on the downward side, with repetition of this process leading to an oscillatory instability.

Incorporating rotation

Since magnetic buoyancy is envisaged as being the mechanism responsible for the instability of the solar toroidal field, it is obviously important to consider the role played by rotation. Interchange modes—which may be regarded as the cartesian analogue of axisymmetric modes in a spherical system—are strongly stabilized by the angular momentum constraint imposed by rotation. Thus, in systems where rotation is of any significance, three-dimensional modes are strongly favored. Furthermore, rotation provides a distinct orientation to the system, with the consequence that instability occurs in the form of travelling waves. In general, for a rotating, diffusive system it is not possible to extract the stability criteria analytically; however, various limiting cases do provide explicit results. For example, when rotation is rapid, and when gravity, rotation and the imposed magnetic field are mutually orthogonal (i.e. a toroidal field at the equator) then ideal (diffusionless) three-dimensional travelling waves are unstable when

$$-\frac{B^2}{\mu_0 p}\frac{\mathrm{d}}{\mathrm{d}z}\ln\left(\frac{B}{\rho}\right) > \frac{\mathrm{d}}{\mathrm{d}z}\ln(p\rho^{-\gamma}). \qquad (9)$$

Coincidentally, this is identical to (5), the criterion for *interchange* modes in the *absence* of rotation.

Discontinuous fields

All of the instability criteria above have addressed the issue of the instability of a smoothly varying magnetic field. A related problem—and one that shows magnetic buoyancy instability in its starkest form—is that of the instability of *discontinuous* magnetic fields. If a slab of magnetic field is embedded in an otherwise field-free atmosphere then the magnetic pressure, and hence also the gas pressure, must be discontinuous at the boundaries of the field. If the temperature is assumed to be continuous (though this is not crucial), then the density at the boundaries of the slab must also be discontinuous. At the upper interface the density jump is destabilizing, with (lighter) magnetic gas supporting (heavier) non-magnetic gas; the gas here is genuinely top-heavy and the resulting instability is of a Rayleigh–Taylor type. (By contrast, at the lower boundary the density jump is stabilizing.) There is no instability criterion as such, all locally top-heavy equilibria being unstable, at least in the absence of diffusion. For a conventional (non-magnetic) Rayleigh–Taylor instability, the preferred mode (in the sense of maximizing the growth rate) has, in the absence of diffusion, infinitesimal horizontal scales. The presence of a magnetic field changes this picture; small scales are preferred in the direction perpendicular to the field, longer scales in the direction along the field. Indeed, once the field is sufficiently strong, interchange modes are preferred.

The nonlinear evolution

The most exciting recent work on magnetic buoyancy instability has been in the study of its nonlinear evolution. In the context of the SOLAR MAGNETIC FIELD, one of the most important questions is whether a large-scale ordered field can break up into smaller-scale field concentrations of the form that might be conveyed to the surface to produce ACTIVE REGIONS. Much of the work on the nonlinear development of magnetic buoyancy instabilities has considered an initial state of a slab of uniform, unidirectional, horizontal magnetic field in a field-free atmosphere (leading to magnetic Rayleigh–Taylor type instabilities) and we shall only discuss this case here. It is instructive first to consider the constrained two-dimensional (interchange) evolution before considering the fully three-dimensional case.

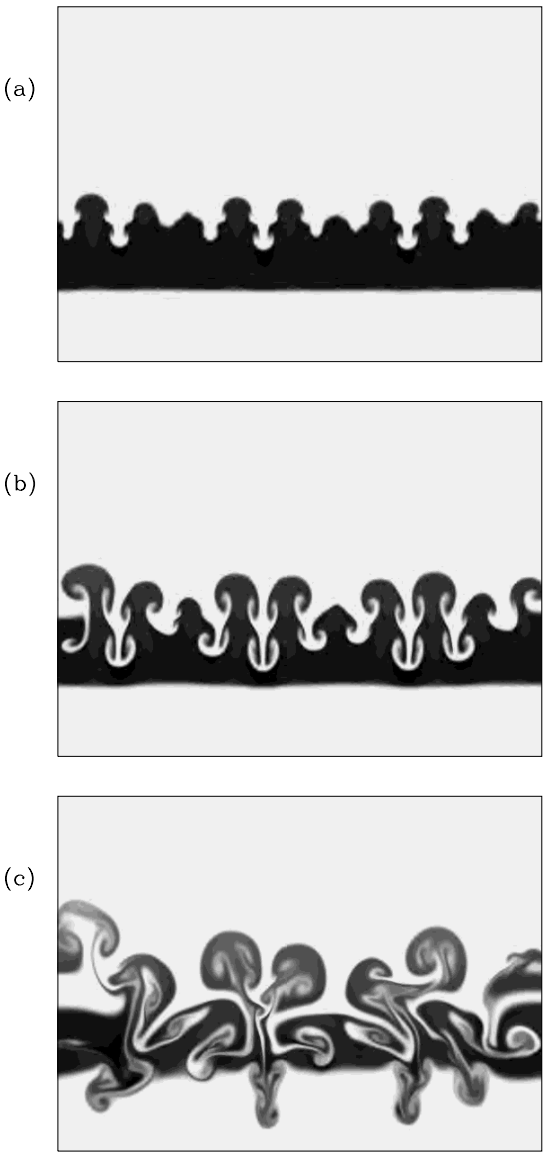

Figure 1. Evolution of the magnetic field for an interchange mode at three diferent times. The field lines are directed into the page. Initially the field occupies the region $0.2 < z < 0.4$.

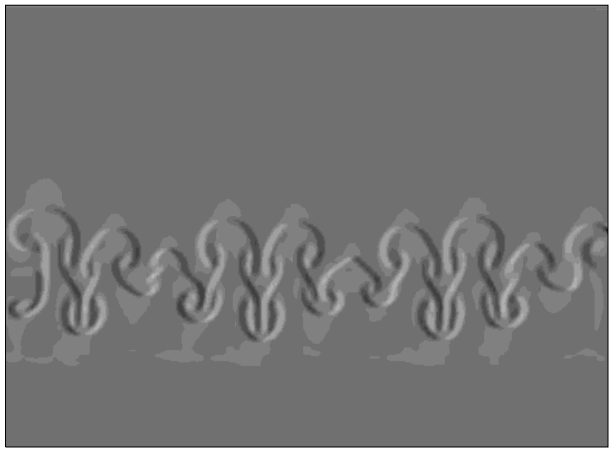

Figure 2. The vorticity corresponding to figure 1(b). Dark (light) shades depict positive (negative) vorticity, with a clockwise (anticlockwise) circulation. It can be seen that the vorticity is concentrated at the mushroom boundaries.

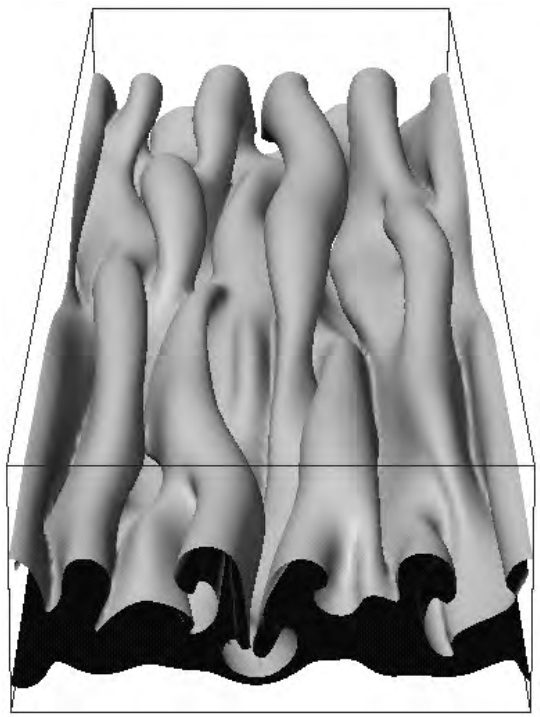

Figure 3. Isosurface of the magnetic field strength for the three-dimensional evolution. Initially the field lines are solely into the page. The cross-sectional cut reveals the mushroom structure perpendicular to the initial field direction. In the third direction, the field has developed undulations as a result of the Crow instability of parallel vortices of opposite sign.

Interchange modes

As mentioned above, instability results from the destabilizing density jump at the upper magnetic interface. The rise of the buoyant magnetic gas and the fall of the overlying denser, non-magnetic gas, results in a shear flow centered on the (moving) magnetic interface. This in turn leads to a secondary Kelvin–Helmholtz instability, which wraps the gas into concentrated patches of vorticity and gives the magnetic field the mushroom shape characteristic of certain Rayleigh–Taylor instabilities (see figures 1 and 2). The subsequent development of the instability is governed, to a large extent, by the interaction of these vortices. The key interactions turn out to be between vortices on neighboring mushrooms—rather than those between vortices on the same mushroom—with the result that the vortices, and their associated magnetic field, are pulled downwards. What is surprising is that the vortex inter-

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

David W Hughes

actions are sufficiently strong as to be able to overcome the intrinsic buoyancy of the magnetic field. As a consequence, there is no wholesale rise of the magnetic field; indeed, pockets of fairly strong field are carried down even below the original lower boundary of the field (figure 1(c)).

Three-dimensional modes

Even when the motions are completely unconstrained, the instability initially evolves in an essentially two-dimensional manner, as described above. Strong vortices are again formed, as a result of a secondary Kelvin–Helmholtz instability, with the vorticity predominantly parallel (or antiparallel) to the initial field. It is in the subsequent vorticity-driven phase that the two- and three-dimensional cases differ strongly. The dominant interactions are again between vortices on neighboring mushrooms. However, whereas for interchange modes this leads to a predominantly downward advection of the vortices, in three dimensions the interactions are such as to drive a further instability, resulting in undulations *along* the vortices. This instability mechanism (known as the crow instability) is precisely that which can sometimes be observed in the interacting trailing vortices of aircraft. Since the magnetic field is closely tied to the fluid, the buckling of the vortices causes a corresponding arched structure in the magnetic field (figure 3). Such a mechanism may be of significance in the development of longitudinal variation in the emerging solar magnetic field.

Future research

This article has concentrated on the fundamental properties of magnetic buoyancy instabilities, an understanding of which has come from the study of fairly straightforward equilibrium configurations. Future research, which will undoubtedly concentrate predominantly on the nonlinear behavior, will seek to explain the role of magnetic buoyancy instability in a somewhat broader context. For example, in the solar interior, where magnetic buoyancy is believed to be responsible for the disruption and escape of the predominantly toroidal field, the influence on the instability of a poloidal field component, of a strong shear, and of the overlying convection, must all be considered.

Magnetic Fields in Stars

Magnetism—the force that deflects the needle of a compass—and magnetic fields have been found in some hundreds of stars during the past 50 yr. Magnetic fields have been detected in T Tauri stars and other pre-main-sequence stars, several types of main sequence stars, white dwarfs and neutron stars. We now know a number of methods by which such magnetic fields may be detected, we are in the process of learning more about how they are distributed over stellar surfaces, and we understand some of the ways in which these fields reflect—and sometimes influence—the evolution of the stars which possess them.

The first stellar magnetic fields were detected in sunspots (see SUNSPOT MAGNETIC FIELDS) in the Sun by George Ellery Hale in 1908. Almost forty years later, in 1947, the first magnetic field in a star other than the Sun was found by Horace W Babcock, who discovered a magnetic field in the star 78 Virginis, a 'chemically peculiar' main sequence star (see STELLAR EVOLUTION) about twice as massive as the Sun. Magnetic fields are now known in perhaps 200 other A and B stars of the middle main sequence, all of which are, like 78 Vir, chemically peculiar (which means that they have very unusual surface chemical compositions). In such stars the fields are generally found to be roughly dipolar in form; in other words, they have an overall structure reminiscent of that of a simple bar magnet or of the Earth's magnetic field, with a north and a south pole, between which the the magnetic force (as represented by magnetic lines of force) points along loops connecting one pole to the other. The typical field strength of such stars—over the whole stellar surface—is of the order of 1000 G (0.1 T), some 3000 times greater than the strength of the Earth's surface field, and about as strong as the magnetic field of a good permanent horseshoe magnet.

The discovery of PULSARS in 1967 by Jocelyn Bell Burnell and Anthony Hewish was soon recognized to be both the discovery of NEUTRON STARS and of magnetic fields in such stars. The pulsed radio radiation emitted by these spinning, magnetized neutron stars is still almost the only means for detecting single neutron stars. The roughly dipolar fields of neutron stars are initially of the order of 10^{12}–10^{13} G (10^8–10^9 T) and then seem to decay in strength by about a factor of 100. Most or all neutron stars thus appear to be formed initially with fields about 10^{10} times stronger than are found in the magnetic middle main sequence stars.

Three years later the first magnetic field was detected in a WHITE DWARF by James Kemp, John Swedlund, John Landstreet and Roger Angel. Fields are now known in about 50 other white dwarfs. These fields range from about 10^5 to 10^9 G (10–10^5 T) in strength, roughly a factor of 10^4 stronger than those of middle main sequence stars. The white dwarf fields also appear to be approximately dipolar in structure. Unlike neutron stars, only a few per cent of all white dwarfs have detectable magnetic fields.

The first magnetic fields in stars of the lower main sequence were detected in 1980 by Richard Robinson, Pete Worden and Jack Harvey. Fields are now known in more than 50 cool stars, mostly rather young, active stars, or in stars in which a companion enforces rapid rotation (see the SOLAR–STELLAR CONNECTION). Recently, fields have been found in a few PRE-MAIN-SEQUENCE STARS and T TAURI STARS. In cool stars, the fields detected have very different distributions over the stellar surface from those of the stellar types already described. Instead of simple, roughly dipolar structure, these fields seem to occur in forms more like giant sunspots, or in patches on the stellar surface that may resemble solar active regions. The field strengths are typically of the order of 10^3 G (0.1 T), while the fraction of the stellar surface covered is typically only of order 20–50%.

Unlike the fields of middle main sequence stars, white dwarfs and neutron stars, all of which are observed to change in structure only very slowly with time, the distribution of magnetic flux on the surface of a lower main sequence star usually changes substantially in a period of weeks or months. It is generally supposed that, in the cool stars, the fields observed are generated by a dynamo process operating in the convective outer envelope of the star, while the more stable fields of middle main sequence stars, white dwarfs and neutron stars are 'fossil fields'—large-scale fields produced during an earlier stage of evolution, and subsequently frozen into the highly electrically conductive matter of the star. In this article we will focus on the fields of middle main sequence stars and of white dwarfs, leaving those of solar-type stars and of neutron stars to other articles.

Methods of detecting stellar magnetic fields

Basic physics

Most of the magnetic fields detected in main sequence and white dwarf stars are found by detecting the ZEEMAN EFFECT in the stellar spectrum. This effect splits each energy level of an atom in a magnetic field into several magnetic substates, leading to a number of effects that can in favorable cases be detected.

When placed in an external magnetic field, a state i of an atom with energy E_i and total angular momentum quantum number J splits into $2J + 1$ magnetic substates equally spaced in energy, with a spacing which varies from one atomic level to another. Transitions between level i and another level f of energy E_f are characterized by the frequency $\nu_{if} = (E_f - E_i)/h$ when no magnetic field is present. When a field B is applied, the splitting of the lower and upper energy levels by the magnetic field leads to the splitting of the spectral line associated with this transition into three closely spaced group of lines. These groups arise because most atomic transitions allow the magnetic quantum number M to change by -1, 0, or 1. The $\Delta M = M_f - M_i = 0$ group, called π components, are distributed symmetrically about ν_{if}. The two groups of lines with $\Delta M = \pm 1$, called σ components, are shifted systematically to frequencies above and below ν_{if}, with the $\Delta M = +1$ group on one side and the $\Delta M = -1$ group

on the other. The typical separation between the π and one of the σ groups is

$$\Delta\lambda_B = \bar{g}eB\lambda^2/4\pi mc^2$$

where $\bar{g}$ is a number of order 1 which varies from one transition to another. In familiar units, the splitting is

$$\Delta\lambda_B(\text{nm}) = 4.67 \times 10^{-3}\bar{g}B(\text{kG})\lambda(\mu\text{m})^2.$$

Thus a field of 1 kG (0.1 T) leads to a π–σ separation of the order of 0.001 nm at 500 nm = 0.5 μm.

The π and σ groups of lines are *polarized*. If the magnetic field is transverse to the line of sight, the π components (in emission) are linearly polarized parallel to the applied field and the σ components are linearly polarized in the orthogonal direction. If the field is parallel to the line of sight, the π components are suppressed and the two groups of σ components have opposite circular polarizations.

When the magnetic field strength is strong enough (of order 10^5 G) that the perturbation of the atom by the field is larger than the spin–orbit perturbation, the relatively complex Zeeman effect is superseded by the Paschen–Back effect, which leads essentially to splitting of all lines into simple triplets. A field of order 10^6 G results in a significant quadratic Zeeman effect, which systematically shifts lines of large upper principal quantum number n_f relative to lines of smaller n_f. As a field of order 10^7 G is reached and the magnetic interaction energy becomes comparable with the Coulomb energy of the atomic electrical field, the atomic spectrum of any atom, even H, becomes extremely complicated.

At fields above about 10^6 G, another magnetic effect occurs that is very useful for detection of fields in white dwarfs: polarization of *continuum* radiation. The broad-band light from a star with a field strength of this order is circularly polarized, essentially because the field forces electrons to spiral about field lines in a preferred direction. For still larger fields, broad-band linear polarization can also occur.

Field measurement methods

The splitting, shifting and polarization of spectral lines by the Zeeman, Paschen–Back and quadratic Zeeman effects, and the occurrence of continuum polarization for sufficiently large fields, have provided astrophysicists with a number of methods of detecting and measuring magnetic fields in stars.

The most straightforward of these methods is useful for stars that have a very small projected equatorial rotational velocity $v_{\text{eq}} \sin i$ and hence sharp spectral lines. In this case, one can directly observe the splitting of spectral lines into components if the field is of the order of a few kilogauss or more in main sequence stars, or about 10^6 G in white dwarfs. The separation of the observed line components provides a direct measurement of the modulus of the magnetic field averaged over the surface of the star, a quantity called the mean field modulus, B_s, as shown in figure 1.

The polarization introduced into spectral lines by magnetic splitting provides a second powerful method of field detection. This method depends on the fact that, in a magnetic field with a significant component along the line of sight, the σ components on one side of the line center absorb circularly polarized light of one sense of polarization, while the σ components on the other side of line center absorb the opposite circular polarization. If we observe the stellar spectrum through polarizers that pass each of the two senses of circular polarization, the absorption lines in one of the two circularly polarized spectra are not at precisely the same wavelengths as the same lines in the other polarized spectrum, because of the small wavelength difference between the two sets of σ components. The presence of a field can be detected by this shift in the position of spectral lines between spectra observed in right- and left-circularly polarized light, or equivalently in the spectrum formed by the difference of the two spectra divided by their sum, as shown in the left-hand panel in figure 2.

The fact that, in the presence of a magnetic field transverse to the line of sight, the absorption by the π components is orthogonally polarized with respect to the polarization of the σ components leads to a similar effect when a spectrum is observed through linear polarizers oriented parallel to and perpendicular to the field direction, as seen in the right-hand panel of figure 2. In general, the observable effect in linear polarization is considerably smaller than in circular polarization.

Detection of the polarization effects from a stellar magnetic field is possible only if there are substantial regions on the stellar surface over which the field does not change direction too much. Clearly, a field structure in which many small tubes of magnetic flux directed out of the star are closely mixed in with small tubes of inward-directed flux will lead to no net polarization, as the effects of adjacent oppositely directed flux tubes will cancel. On the other hand, the detection of circular polarization, which is not readily produced in line profiles by other mechanisms, is a very robust indicator of the presence of a field. Furthermore, very small levels of polarization (0.1% or even 0.01%) can be measured reliably. The result is that circular polarization methods, which measure what is called the 'mean longitudinal field' B_ℓ, provide much more sensitivity to weak but geometrically simple magnetic fields than methods that depend on studying line profiles. In the best cases, B_ℓ values as small as tens of gauss can presently be detected.

Magnetic fields in middle main sequence ('peculiar A') stars

The oblique rotator

Magnetic fields are detected in middle main sequence stars (stars of between about 2 and 10 times the mass of the Sun, which are burning hydrogen in their cores) both by the detection of circular polarization in spectral

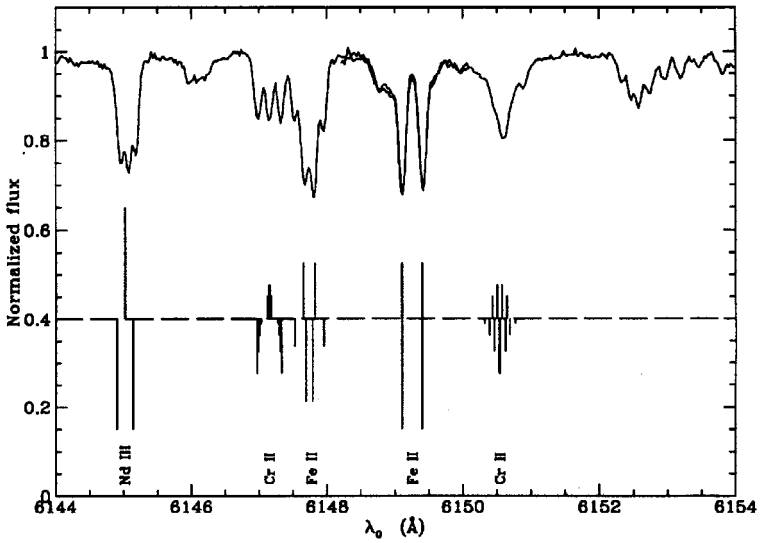

Figure 1. A portion of the spectrum of the very slowly rotating magnetic Ap star HD 94660 (the spectrum at the top of the figure), showing splitting of spectral lines by a magnetic field of $B_s \approx 6400$ G. Below the stellar spectrum is a schematic diagram of the Zeeman splitting pattern of several strong stellar spectral lines. Each of the vertical lines above and below the line at intensity 0.4 (respectively π and σ components) represents one Zeeman component; the position of each component is calculated for a field of 6400 G, and the height of each line is proportional to the strength of that component. The ion responsible for each strong line is identified at the bottom of the figure. (From G Mathys 1990 *Astron. Astrophys.* **232** 151, reproduced by permission of *Astronomy and Astrophysics*.)

lines and by observing Zeeman splitting of spectral lines in stars with small $v_{\rm eq} \sin i$ values. All well-confirmed detections of fields in middle main sequence stars are in members of a class of stars known as 'chemically peculiar A stars', often called Ap (or Bp) stars (see also PULSATING AND CHEMICALLY PECULIAR UPPER MAIN SEQUENCE STARS). These stars have long been known to have (sometimes very) anomalous atmospheric chemical composition compared with the Sun. Their chemistry is typically characterized by unusually large amounts of chemical elements such as Sr, Cr, Eu and other rare earths, Si and (only in the most massive Bp stars) He. Most of these stars also have unusually small amounts of a few elements as well, often He and O. The elements which are anomalous depend systematically on the mass of the star. It appears that all chemically peculiar stars having the same general chemical anomalies as the known magnetic stars probably have fields.

A first question about the magnetic middle main sequence stars (I will call them 'magnetic Ap stars') is that of determining the geometry of the magnetic field over the stellar surface. This cannot be determined by directly observing the disks of such stars, of course; they are much too small in angular size for direct imaging. We must use other kinds of information to deduce the magnetic geometry.

The magnetic Ap stars are in most cases observed to vary periodically in apparent brightness, in the strengths and profiles of some or most spectral lines, and in the measured components of the magnetic field. All these quantities are generally observed to vary with the same period. The period of variations is typically in the range 1–10 days, although periods as short as 0.5 days and as long as some decades or known. An example is shown in figure 3.

An important clue to the origin of the variations is furnished by the observed fact that the value of the projected rotational velocity $v_{\rm eq} \sin i$ is closely correlated with the period of variation. Large values of $v_{\rm eq} \sin i$ are *only* found for stars with short periods and, the longer the period, the smaller the values of $v_{\rm eq} \sin i$ are. The facts that the observed periods are found with an enormous range of values and that the periods are closely related to the projected rotational velocities clearly indicate that the observed variations are due to the *rotation* of the magnetic Ap star. Variation in the average magnetic field indicates that the star must have a magnetic field that varies from one place to another at the surface, either in strength or in inclination or both. Thus, when we see mainly magnetic field lines directed towards the observer, we measure a large value of B_ℓ, but, when the field lines are mainly perpendicular to the line of sight, B_ℓ is small. The variations in spectral line intensity and shape indicate that the relative abundances of various chemical elements vary from one place on the star to another. When we are looking at a part of the star in which some element (such as He) is relatively abundant, the spectral lines are strong and deep; when we look at a different part of the star which has relatively less He, the spectral lines are weaker. The variations in surface chemistry in turn influence the amount of light emitted at various wavelengths and lead to the variations observed in brightness as the star rotates.

We observe that the value of B_ℓ of a magnetic Ap star generally varies in a fairly sinusoidal fashion. When we

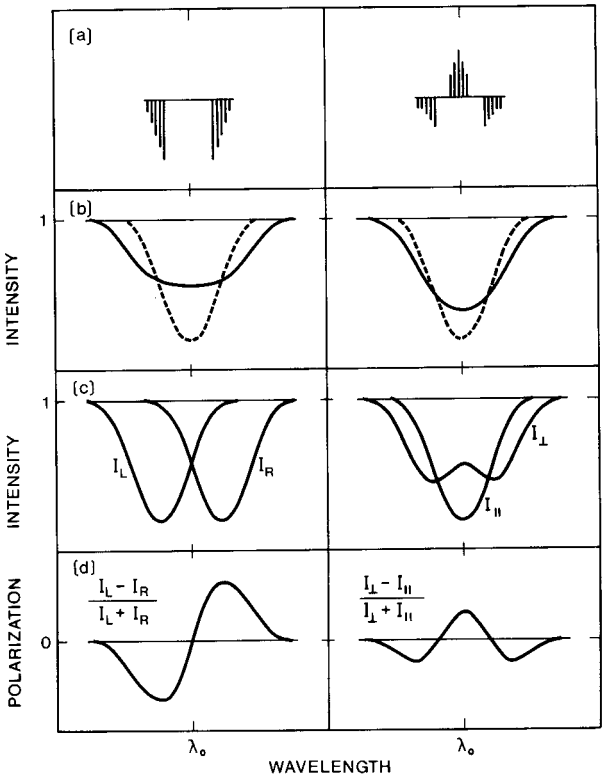

Figure 2. Effects of a magnetic field on the line profile and polarization of stellar spectral lines. The panels show schematically the effect of a magnetic field with the Zeeman pattern displayed in (*a*) for a field parallel to the line of sight (left) and perpendicular to it (right). (*b*) The change in the line from the non-magnetic case (dotted) to the magnetic case (solid) for Zeeman splitting comparable with the Doppler width of the spectral line. (*c*) The absorption line in left- and right-circular polarization (left) and in linear polarization parallel to and perpendicular to the stellar field (right). (*d*) The net circular (left) and linear (right) polarization in the line. (From D J Landstreet 1980 *Astron. J.* **85** 611, reproduced by permission of the American Astronomical Society.)

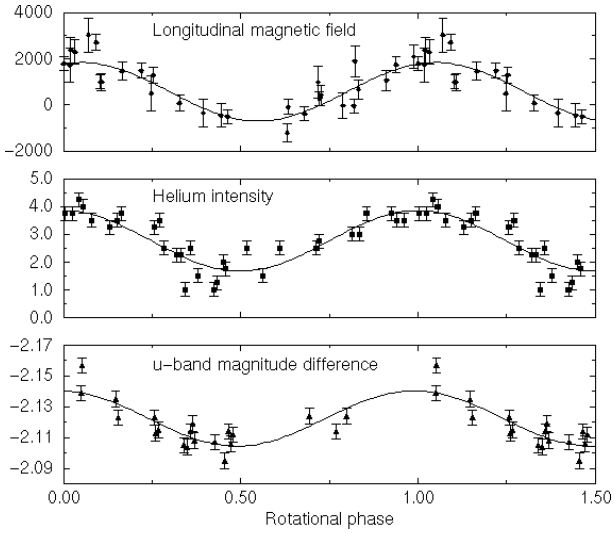

Figure 3. Variations of the massive magnetic Bp star HD 184927 (whose most striking abundance peculiarity is a considerable excess of atmospheric He) with a period of 9.53 days. The horizontal axis gives time in phase units (fractions of one cycle from the periodically repeating time when the helium spectral line intensities are strongest). The three panels show (from top to bottom) the mean longitudinal field in kilogauss, the strength of one helium line in arbitrary units and the brightness of the star (in magnitudes) seen through a narrow (Strömgren) ultraviolet filter. (From G A Wade *et al* 1997 *Astron. Astrophys.* **320** 172, reproduced by permission of *Astronomy and Astrophysics*.)

try to reproduce this behavior by calculating the variations expected from various simple models of the field geometry, we find that this observation is consistent with the idea that the structure of the magnetic field over the surface of the star is in the general form of a dipole, typically inclined (oblique) to the rotation axis of the star by some fairly large angle. As the star rotates, we thus usually see one pole of the dipolar distribution, and then the other. This model is known as the 'oblique rotator model'.

Astronomers are also actively working to use observed spectrum variations to deduce the distributions of different chemical elements over the surface of the star. Often the models that fit the observations have a distribution of the elements that is roughly axisymmetric around the axis of the magnetic dipole. It is not uncommon to find very large differences in the fractional abundances of some elements over the stellar surface; in some cases there may be more than 100 times more atoms of some elements per unit volume of gas in one part of the star's atmosphere than in another part.

Origin of the observed magnetic fields and of the chemical anomalies

Astronomers generally accept two possible origins for observed stellar fields. One is that a field may be generated by the interplay between convection (boiling motions of the gas) in the outer layers of a star and the overall rotation of the star. These motions may act as a dynamo in the highly conducting outer layers of a star, producing a complex and time-varying field. This mechanism seems to be the cause of the magnetic field observed in the Sun. In spite of much theoretical effort, such dynamo fields are still not well understood.

The second possible origin is that the field is the result of the collapse of a huge gas cloud to form a tiny star, trapping in the partly ionized, electrically conducting gas some small fraction of the weak galactic magnetic field. As the field lines of the galactic field are squeezed together, the strength of the entrained field is amplified by a very large factor. Thus, the observed fields of the magnetic Ap stars may be 'fossil' magnetic fields. This is not as unreasonable an idea as may at first appear. Owing to the very large bulk and high electrical conductivity of a star, a field formed in this way would take a very long time, of the order of 10^{10} yr, to decay. This is longer than the main sequence lifetime

of a middle main sequence star, and so a fossil field could easily persist throughout the life of such a star.

The absence of any long-term changes in the observed magnetic field strengths of magnetic Ap stars (such as the solar activity cycle), other than the periodic variations caused by stellar rotation, and the simple overall geometry deduced for these fields, suggests that they are probably fossil fields rather than dynamo-generated ones. This view is supported by the lack of any obvious means of generating a large dynamo field in a star that may be rotating 100 times slower than the Sun and that has almost no convection in its outer layers.

The presence of remarkable chemical peculiarities in these magnetic stars also requires an explanation. In fact, this is not quite as anomalous as it seems. The lower-mass stars of the main sequence ($M \leq 2M_{\odot}$) show quite homogeneous abundance patterns, with overall content of 'heavy elements' (everything heavier than He) that depends only on the age of the star. (Older low-mass stars, formed when the universe was less rich in the elements synthesized in many generations of supernova explosions, have less of all heavy elements than younger stars.) Very massive main sequence stars ($M \geq 10M_{\odot}$) lose mass rapidly, and this ensures that their surfaces reveal their bulk composition which, because of their very short main sequence lifetimes, is essentially that of the contemporary interstellar material from which they form. The intermediate-mass stars, among which the magnetic Ap stars are found, almost all exhibit some degree of chemical individuality. In most A and B stars the variations are no more than some tens of per cent of excess or deficiency compared with other similar stars, but several other families of stars (mostly slowly rotating and apparently non-magnetic stars) are known in which certain deficiencies or enhancements can reach much larger values. 'Metallic-line A' (Am) stars often have 10 times less Ca and Sc than other main sequence stars of similar mass, and 10 times more of some rare earths. 'Mercury–manganese' (HgMn) stars have enhancements of some elements by factors of from order 10^2 (V, Mn, Ga) up to 10^5 or more (Eu, Pt, Hg). The abundance anomalies of the magnetic Ap stars are simply some of the most spectacular types of anomaly in a mass range filled with variety.

These chemical abundance anomalies are generally believed to be confined to the atmospheres and outer envelopes of intermediate-mass stars, rather than being representative of the bulk chemical composition of these stars, for several reasons. First, the wide variety of observed compositions, in stars all of which formed relatively recently in galactic history, does not correspond to any similar variety of compositions in the interstellar clouds which form stars, or in other young stars of low or high mass. Furthermore, the extremes of anomaly are so great (factors of 10^5 or more) that it is not possible to imagine any way in which star formation could have led to gas clouds with such peculiar composition. Instead, we believe that the observed chemical anomalies are essentially surface phenomena, due to powerful processes that *separate* elements, raising some into the atmosphere while others sink out of sight.

The main sorting process leading to chemical anomalies is microscopic diffusion of atoms of low-abundance elements, relative to the dominant hydrogen of the stellar gas. Under the influence of gravity, elements with higher atomic mass than hydrogen tend to sink into the interior of the star. In a sufficiently stable atmosphere, this process would eventually lead to an exterior layer made up only of hydrogen, as is actually observed in many white dwarfs. However, there are competing processes. One of the most important is the outward force felt by atoms and ions which can absorb photons of many wavelengths from the outward flow of radiation through the star. This absorption imparts an outward acceleration to such ions and lifts them up to higher levels in the stellar envelope. Thus, the overall effect of diffusion is to allow some elements to sink in the atmosphere under the dominant influence of gravity, while others are lifted towards the surface by radiation.

These sorting processes compete with various mixing processes such as convection. Thus, because the outer layers of low-mass main sequence stars are strongly convective, all sorting processes are strongly inhibited, and these Sun-like stars exhibit very similar compositions.

In contrast, the main sequence stars of intermediate mass are precisely the stars with sufficiently stable atmospheres to allow diffusion to sort the chemical elements, at least to some extent. Rapid rotation is capable of generating slow mixing currents, and so the more rapidly rotating A and B stars have only modestly sorted surface chemistries. Most of the more peculiar middle main sequence stars are slowly rotating. The magnetic Ap stars have the additional feature that the presence of the magnetic field rather strongly inhibits mixing motions in the outer layers. The chemical peculiarities of the magnetic Ap stars are simply a particularly strongly developed aspect of a characteristic found in all stars in this mass range.

Magnetic fields in white dwarfs

Observations and modelling

Magnetic fields are detected in white dwarfs by the same methods used for magnetic Ap stars, namely by direct observation of magnetic splitting of spectral lines and by observation of circular polarization in line wings. Fields are also detected by means of the continuum polarization produced by fields of more than about 10^6 G. The deduced fields range in strength from about 10^5 up to 10^9 G. At the low end of this range, the spectrum of a white dwarf is hardly perturbed at all by the field. For fields in the range from about 10^6 to 3×10^7 G, splitting of familiar spectral lines is easily seen. For still larger fields, the wavelengths and shapes of spectral lines are so strongly altered by the field that the spectrum is not recognizably related to that of any non-magnetic white dwarf. The spectrum of one magnetic white dwarf is shown in figure 4.

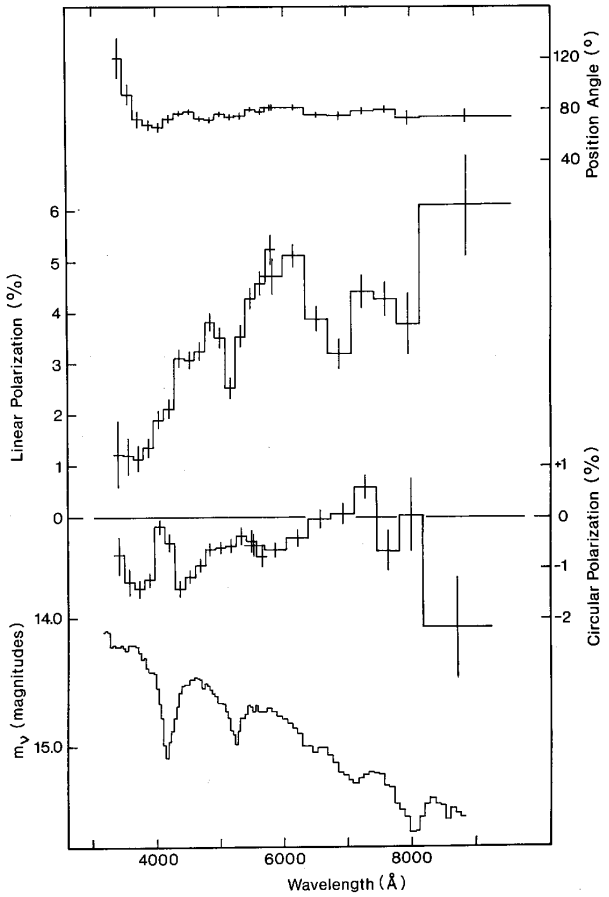

Figure 4. The flux and polarization spectrum of the magnetic white dwarf GD 229, which has a field of order 10^9 G. The lowest curve shows the wavelength variation of the flux, the second lowest of circular polarization, the third lowest the percentage linear polarization and the top the position angle of linear polarization.

The polarization and/or line splitting is observed to be variable in about one-quarter of the known magnetic white dwarfs. Observed variations are periodic, with periods in the range from about 1 h to 20 days. These periods are so long compared with any reasonable oscillation period of a white dwarf that they must be rotation periods, and so we are again quickly led to the oblique rotator model for the variations. The observed variations in the magnetic field strength and in spectral line shapes are again interpreted as simply being due to the fact that we see a magnetic field that is inclined to the stellar rotation axis from different directions as the star rotates. The fact that most magnetic white dwarfs do *not* vary may imply that, in most magnetic white dwarfs, the magnetic field is axisymmetric about the rotation axis or possibly that most magnetic white dwarfs rotate with periods of decades or more.

Modelling of observed spectra and their variations is possible if the fields are not too large, say not much more than about 3×10^7 G. Modelling of such fields leads to deduced magnetic field geometries that are roughly dipolar, like the fields of magnetic Ap stars. For stronger fields, the main difficulties come from the complex and uncertain behavior of even simple atoms such as H in the presence of fields so strong that they influence the motion of the electron(s) as strongly as the central Coulomb attraction of the atomic nucleus. The observations of spectra of white dwarfs with fields of 10^8 G or more are in reasonable accord with the results of atomic physics calculations, but no detailed modelling has yet been possible.

Fields as small as about 10 kG could be detected in most white dwarfs. Surveys of many white dwarfs to about this level of precision have shown that the great majority of white dwarfs do not possess detectable magnetic fields. About 4% of the total population of white dwarfs have fields, with about equal probabilities per decade of field strength over the range 10^5–10^9 G.

Origin of white dwarf fields

Trying to understand the origin of the fields observed in white dwarfs presents us with substantial challenges. There are no obvious mechanisms for producing large-scale, ordered, static fields in either magnetic Ap stars or white dwarfs after they are formed. We observe that a small fraction of middle main sequence stars, and of white dwarfs, have magnetic fields large enough to detect, in the range 10^2–10^5 G on the main sequence and 10^5–10^9 G in white dwarfs. The observed magnetic Ap fields may be due to magnetic flux retention during star formation, and the fields of white dwarfs could be due to the further retention of that same flux as magnetic Ap stars collapse to become white dwarfs. This hypothesis is consistent to some extent with the relative values of observed field strength, since, if the magnetic flux Φ threading a star's equator is retained during a collapse, the magnetic field strength will increase as

$$B \propto \Phi / R^2$$

where R is the stellar radius. Thus the decrease in radius by a factor of 10^2 as a star becomes a white dwarf could lead to a field strength increase by a factor of 10^4, about the difference observed between the ranges of field strength on the main sequence and among white dwarfs. However, this does not explain how that magnetic flux is retained in the evolution stages between the main sequence and white dwarf stages; the intervening giant state is expected to be largely convective, which might be expected to expel much of the magnetic flux in a star. Furthermore, this idea does not explain why the largest (10^8–10^9 G) fields are as common as fields 10^3 times smaller; on the main sequence the largest fields are a modest tail on a distribution that is very strongly peaked around fields of less than 10^3 G.

Magnetic fields in neutron stars present us with further challenges. It appears that almost all neutron stars have fields of the order of 10^{10}–10^{13} G. Again, these are

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

about the fields that would be expected by magnetic flux retention from the main sequence. However, if this is the origin of magnetic fields in neutron stars, why do almost *all* neutron stars have large fields, while only a small fraction of white dwarfs have large fields? This question is made still more puzzling by the fact that virtually no magnetic main sequence stars are known in the mass range that is expected to evolve eventually to neutron stars.

Magnetic Helicity

Magnetic helicity measures structural properties of a magnetic field such as twist, shear, linking and braiding. It is conserved in the limit of infinite electrical conductivity. In a PLASMA with high conductivity (magnetic Reynolds number $R_m \gg 1$) reconnection preserves magnetic helicity to an excellent approximation.

Magnetic helicity has proven to be a valuable tool for both observers and theorists. It provides a common measure of topological structure. Thus the net twist of field lines within a CORONAL LOOP and the net shear of a coronal arcade can be directly compared. Its conservation provides a constraint on the evolution of a magnetic field. For example, suppose a field undergoes a series of MAGNETIC RECONNECTIONS. Each reconnection takes energy away from the field. If this process continues until no more energy is available, then the final state will have the minimum possible energy given the magnetic helicity and the boundary conditions. This process is known as Taylor relaxation; the final state is generally a linear FORCE-FREE MAGNETIC FIELD.

A field region with large magnetic helicity, whether or not it is force free, stores substantial amounts of energy and exerts pressure on its surroundings. If a region of the solar CORONA begins to build up excessive helicity, then the surrounding fields and plasmas may not be able to confine it. A SOLAR CORONAL MASS EJECTION may then release the excess helicity and energy into the SOLAR WIND.

Magnetic helicity and field topology

Early in the 19th century Gauss discovered an integral which measures the linking of two curves. He employed this integral first to describe the paths of asteroids whose orbits link the Earth's orbit and later to study linked electrical circuits. For two closed directional curves the linking number L counts how many times one curve passes through the other (see figure 1). One way of calculating L without integration involves looking at a drawing of the curves, i.e. a projection onto a plane, and examining the places where one curve crosses over the other. For each crossing, orient the drawing so that the overlying curve points to the right. Assign the crossing the number +1 if the underlying curve points upwards and -1 if it points downwards. The linking number L equals one-half the sum of these numbers over all crossings.

The magnetic helicity inside a region $\mathcal{V}$ is, in essence, the sum of linking numbers over all pairs of field lines within $\mathcal{V}$. To begin with, consider a magnetic field consisting of N tubes of magnetic flux. For now, assume that each tube closes upon itself within $\mathcal{V}$. Each tube has flux $F_i, i = 1, \ldots, N$, and tubes i and j have linking number L_{ij}. Then the helicity

$$K = \sum_{i=1}^{N} \sum_{j=1}^{N} L_{ij} F_i F_j. \qquad (1)$$

The diagonal terms $L_{ii} F_i^2$ measure linking of field lines within the same tube. If the field lines in tube i all twist about a central axis then a typical field line makes L_{ii} turns about the axis.

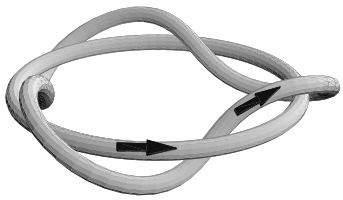

Figure 1. Two linked magnetic tubes with linking number $L = 3$.

Note the analogy with magnetic inductance: the energy of N circuits carrying currents $I_1, \ldots, I_N$ is proportional to $\sum_{i=1}^{N} \sum_{j=1}^{N} M_{ij} I_i I_j$, where M_{ii} is a self-inductance and M_{ij} is a mutual inductance. Thus we may call $L_{ii} F_i^2$ the self-helicity of tube i and $2L_{ij} F_i F_j$ the mutual helicity between tubes i and j.

A magnetic surface is a surface $\mathcal{S}$ where the normal component of the magnetic field vanishes, $\boldsymbol{B} \cdot \hat{\boldsymbol{n}}|_{\mathcal{S}} = 0$. If $\mathcal{V}$ is bounded by such a surface, then the magnetic field is called closed: as no field line can escape through $\mathcal{S}$, each line must close upon itself or come arbitrarily close to doing so. Thus to an approximation the field can be described by a collection of N closed flux tubes. In the limit $N \to \infty$ the approximation becomes exact; meanwhile the double-sum expression for K turns into a double integral

$$K_{\mathcal{V}} = \int_{\mathcal{V}} \boldsymbol{A} \cdot \boldsymbol{B} \, \mathrm{d}V$$

where

$$\boldsymbol{A}(\boldsymbol{x}) = -\frac{1}{4\pi} \int_{\mathcal{V}} \frac{(\boldsymbol{x} - \boldsymbol{x}') \times \boldsymbol{B}(\boldsymbol{x}')}{|\boldsymbol{x}' - \boldsymbol{x}|^3} \, \mathrm{d}V'.$$

The vector potential $\boldsymbol{A}(\boldsymbol{x})$ satisfies $\boldsymbol{\nabla} \times \boldsymbol{A} = \boldsymbol{B}$; the above integral form also satisfies $\boldsymbol{\nabla} \cdot \boldsymbol{A} = 0$. A gauge transformation $\boldsymbol{A} \to \boldsymbol{A} + \boldsymbol{\nabla}\phi$ will not change K, provided that $\mathcal{V}$ is bounded by a magnetic surface. The magnetic helicity of open fields will be defined below.

Care must be taken if $\mathcal{V}$ is multiply connected, i.e. has a hole like a doughnut. In this case there are vector fields $\boldsymbol{G}$ where $\boldsymbol{\nabla} \times \boldsymbol{G} = \boldsymbol{0}$ but $\boldsymbol{G} \neq \boldsymbol{\nabla}\phi$ for any single-valued function ϕ. (For example if ϕ represents angle in polar coordinates then it is not single valued.) Gauge transformations $\boldsymbol{A} \to \boldsymbol{A} + \boldsymbol{G}$ will indeed change K.

Other helicities

Given any two divergence-free vector fields $\boldsymbol{V}$ and $\boldsymbol{W}$ ($\boldsymbol{\nabla} \cdot \boldsymbol{V} = \boldsymbol{\nabla} \cdot \boldsymbol{W} = 0$) we can define a helicity integral which measures their mutual linking. Assume here that $\mathcal{V}$ is all of space or that its boundary $\mathcal{S}$ provides a closed surface for both fields ($\boldsymbol{V} \cdot \hat{\boldsymbol{n}}|_{\mathcal{S}} = \boldsymbol{W} \cdot \hat{\boldsymbol{n}}|_{\mathcal{S}} = 0$). Their helicity is then defined by

$$H_{\mathcal{V}}(\boldsymbol{V}, \boldsymbol{W}) = H_{\mathcal{V}}(\boldsymbol{W}, \boldsymbol{V}) = \int_{\mathcal{V}} \boldsymbol{A}_{\boldsymbol{V}} \cdot \boldsymbol{W} \, \mathrm{d}V \qquad (2)$$

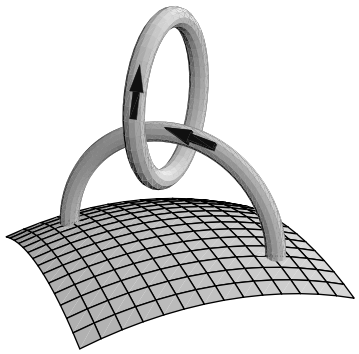

Figure 2. A loop linking a closed tube.

where $\boldsymbol{\nabla} \times \boldsymbol{A_V} = \boldsymbol{V}$. For example $K_\mathcal{V} = H_\mathcal{V}(\boldsymbol{B}, \boldsymbol{B})$.

Suppose $\mathcal{V}$ contains a fluid with flow velocity $\boldsymbol{v}$. If $\boldsymbol{V}$ and $\boldsymbol{W}$ are transported by $\boldsymbol{v}$ without diffusion (e.g. $\partial \boldsymbol{V}/\partial t = \boldsymbol{\nabla} \times (\boldsymbol{v} \times \boldsymbol{V})$) then their helicity will be conserved, $\mathrm{d}H_\mathcal{V}(\boldsymbol{V}, \boldsymbol{W})/\mathrm{d}t = 0$. Thus $K_\mathcal{V}$ is conserved in an infinitely conducting plasma. Similarly, a fluid with zero viscosity transports the vorticity $\boldsymbol{\omega} = \boldsymbol{\nabla} \times \boldsymbol{v}$ without diffusion; the flow thus conserves the kinetic helicity

$$H_\mathcal{V}(\omega, \omega) = \int_\mathcal{V} \boldsymbol{v} \cdot \boldsymbol{\omega}\, \mathrm{d}v.$$

The general helicity formula (2) is linear in each term, e.g.

$$H_\mathcal{V}(a\boldsymbol{V}_1 + \boldsymbol{V}_2, \boldsymbol{W}) = aH_\mathcal{V}(\boldsymbol{V}_1, \boldsymbol{W}) + H_\mathcal{V}(\boldsymbol{V}_2, \boldsymbol{W}).$$

Magnetic helicity in an open volume

A vector field $\boldsymbol{V}$ in a volume $\mathcal{V}$ with boundary $\mathcal{S}$ is open if some of its flux crosses the boundary, i.e. $\boldsymbol{V} \cdot \hat{n}|_\mathcal{S} \neq 0$ somewhere on $\mathcal{S}$. The concept of linking will now be extended from closed fields to open fields. We first note that a closed curve may link an open curve, as in figure 2. Similarly, if $\boldsymbol{V}$ is open, but $\boldsymbol{W}$ is closed, then we may still employ the formula (2) to measure the linking of $\boldsymbol{V}$ and $\boldsymbol{W}$. Here the vector potential in the integral must always refer to the open field to ensure gauge invariance. (By Stokes' theorem the line integral of $\boldsymbol{A_V}$ about a closed field line of $\boldsymbol{W}$, i.e. $\oint \boldsymbol{A_V} \cdot \boldsymbol{W}|\boldsymbol{W}|^{-1}\, \mathrm{d}\ell$, equals the net flux of $\boldsymbol{V}$ linked by the $\boldsymbol{W}$ line. Integrating over the $\boldsymbol{W}$ flux leads to equation(2).)

Our strategy for measuring the magnetic helicity of an open magnetic field $\boldsymbol{B}$ will be to decompose $\boldsymbol{B}$ into a closed field and an open field with minimal structure, then sum the self- and mutual helicities of these fields. Of the many possible fields inside $\mathcal{V}$ consistent with the boundary flux $\boldsymbol{B} \cdot \hat{\boldsymbol{n}}|_\mathcal{S}$, one unique field minimizes the total magnetic energy: the potential field $\boldsymbol{P}$ where $\boldsymbol{\nabla} \times \boldsymbol{P} = \boldsymbol{0}$. This field has zero current inside $\mathcal{V}$; its source currents must exist outside of $\mathcal{V}$ or as surface currents in $\mathcal{S}$. Owing to its unique properties, we choose $\boldsymbol{P}$ to be our open field.

We decompose $\boldsymbol{B}$ into the sum of the potential field $\boldsymbol{P}$ and the closed field

$$\boldsymbol{B}_{cl} = \boldsymbol{B} - \boldsymbol{P} \qquad \boldsymbol{B}_{cl} \cdot \hat{n}|_S = 0.$$

Then

$$\begin{aligned} K_\mathcal{V} &= H_\mathcal{V}(\boldsymbol{B}, \boldsymbol{B}) \\ &= H_\mathcal{V}(\boldsymbol{B}_{cl}, \boldsymbol{B}_{cl}) + 2H_\mathcal{V}(\boldsymbol{P}, \boldsymbol{B}_{cl}) + H_\mathcal{V}(\boldsymbol{P}, \boldsymbol{P}). \end{aligned}$$

The first two terms measure the self-linking of a closed field and the mutual linking between an open and a closed field. Both of these are well defined by equation (2). Unfortunately, the last term cannot be defined by equation (2) without ambiguity. The accepted procedure simply assigns the value 0 to $H_\mathcal{V}(\boldsymbol{P}, \boldsymbol{P})$. A similar procedure assigns zero voltage to Earth in an electrical circuit. As the potential field $\boldsymbol{P}$ occupies the minimum energy state of $\mathcal{V}$, the assignment of zero helicity is natural. With this definition the helicity becomes

$$K_\mathcal{V} = \int_\mathcal{V} (\boldsymbol{A} + \boldsymbol{A_P}) \cdot (\boldsymbol{B} - \boldsymbol{P})\, \mathrm{d}V. \tag{3}$$

Helicity dissipation

Suppose the boundary flux $\boldsymbol{B} \cdot \hat{\boldsymbol{n}}|_\mathcal{S}$ is fixed. Then no helicity can cross the boundary and the helicity can only change as a result of dissipation (see next section for transfer of helicity across boundaries). We will use Ohm's law to express the electric field in terms of the electric current and the magnetic diffusivity, $\boldsymbol{E} = \eta \boldsymbol{J}$.

From the definition of $K_\mathcal{V}$ (equation (3)) and Maxwell's equations

$$\frac{\mathrm{d}K_\mathcal{V}}{\mathrm{d}t} = -2 \int_\mathcal{V} \eta \boldsymbol{J} \cdot \boldsymbol{B}\, \mathrm{d}V.$$

Note that the magnetic energy is proportional to $W_\mathcal{V} = \int_\mathcal{V} B^2\, \mathrm{d}V$ with dissipation $|\mathrm{d}W_\mathcal{V}/\mathrm{d}t| = 2\int_\mathcal{V} \eta J^2\, \mathrm{d}V$. Thus, using a Schwarz inequality,

$$\left|\frac{\mathrm{d}K_\mathcal{V}}{\mathrm{d}t}\right| \leq \left(2\eta W_\mathcal{V} \left|\frac{\mathrm{d}W_\mathcal{V}}{\mathrm{d}t}\right|\right)^{1/2}. \tag{4}$$

In order to apply this inequality to reconnection events, define a length scale $L \equiv |K_\mathcal{V}|/W_\mathcal{V}$. This length is comparable with the size of the volume if the magnetic field has significant helical structure. For example, a linear force-free field inside a spherical magnetic surface of radius R has $L \approx 0.31R$. A dissipation time τ_d can now be defined as $\tau_d = L^2/\eta$. Consider an arbitrary reconnection or dissipation process occurring over a time Δt in an isolated volume. Integrating equation (4) over time gives

$$\left|\frac{\Delta K}{K}\right| \leq \left(\frac{\Delta t}{\tau_d}\right)^{1/2}. \tag{5}$$

Thus for any fast reconnection event ($\Delta t \ll \tau_d$), ΔK will be negligible. For flares in the solar corona with

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

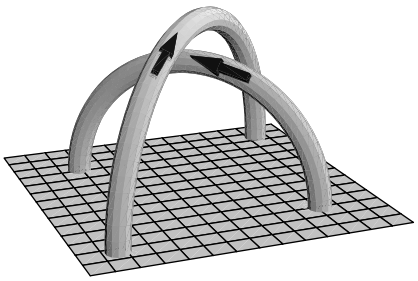

Figure 3. Two crossed loops.

$\Delta t \approx 1000$ s, $L \approx 10^3$ km and $\eta \approx 10^{-6}$ km^2 s^{-1} we find $\tau_d \approx 10^{12}$ s, and $|\Delta K/K| < 3\times10^{-5}$. In practice, even these small limits significantly overestimate ΔK, as they make no assumptions about the reconnection geometry. As a crude estimate, if we assume that reconnection takes place only in a small fraction ϵ of the total volume then we can effectively replace η by $\epsilon\eta$ and τ_d by τ_d/ϵ. Then the bound (5) on ΔK has an additional factor $\epsilon^{1/2}$.

Helicity transport

In this section we ignore dissipation and consider the transport of helicity across a boundary S due to fluid motions. Let $\boldsymbol{v}$ be the fluid velocity. Also recall that $\boldsymbol{A_P}$ is a vector potential for $\boldsymbol{P}$. Inside $\mathcal{V}$, let $\widetilde{\boldsymbol{A}}_{\boldsymbol{P}}$ be the unique vector potential satisfying $\boldsymbol{\nabla}\cdot\widetilde{\boldsymbol{A}}_{\boldsymbol{P}} = 0$, $\widetilde{\boldsymbol{A}}_{\boldsymbol{P}}\cdot\hat{n}|_S = 0$. Then one can show that

$$\frac{\mathrm{d}K_{\mathcal{V}}}{\mathrm{d}t} = 2\oint_S[(\widetilde{\boldsymbol{A}}_{\boldsymbol{P}}\cdot\boldsymbol{v})\boldsymbol{B} - (\widetilde{\boldsymbol{A}}_{\boldsymbol{P}}\cdot\boldsymbol{B})\boldsymbol{V}]\cdot\mathrm{d}\boldsymbol{S}.$$

The first term measures the effect of motions parallel to the boundary, whereas the second measures the effect of motion across the boundary.

If S is the plane $z = 0$ and $\mathcal{V} = \{z > 0\}$, then one finds

$$\widetilde{\boldsymbol{A}}_{\boldsymbol{P}}(\boldsymbol{x}) = \frac{1}{2\pi}\int_{\mathrm{S}}\frac{B_z(\boldsymbol{x}')}{r}\hat{\boldsymbol{\theta}}_{\boldsymbol{x}\boldsymbol{x}'}\,\mathrm{d}S$$

where $\boldsymbol{r} = \boldsymbol{x} - \boldsymbol{x}'$ and $\hat{\boldsymbol{\theta}}_{\boldsymbol{x}\boldsymbol{x}'} = \hat{\boldsymbol{z}}\times\hat{\boldsymbol{r}}$ is the angular direction at $\boldsymbol{x}$ about the integration point $\boldsymbol{x}'$. For example, suppose the flux through $z = 0$ consists of two flux tubes of flux F_1, F_2 centered at $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. Suppose these tubes rotate with angular velocities w_1 and w_2. Also suppose that the tubes move about each other with angular velocity $\mathrm{d}\theta_{12}/\mathrm{d}t = [\boldsymbol{v}(\boldsymbol{x}_1) - \boldsymbol{v}(\boldsymbol{x}_2)]\cdot\hat{\boldsymbol{\theta}}_{\boldsymbol{x}\boldsymbol{x}'}$. Then

$$\frac{\mathrm{d}K_{\mathcal{V}}}{\mathrm{d}t} = -\frac{1}{2\pi}\left(w_1F_1^2 + w_2F_2^2 + 2\frac{\mathrm{d}\theta_{12}}{\mathrm{d}t}F_1F_2\right). \qquad (6)$$

The first two terms describe the twisting of individual tubes, while the final term describes mutual braiding.

Helicity of coronal loops

The helicity transport equations often greatly simplify calculations. The helicity of a field depends only on its present geometry and ignores its past history. To illustrate, we calculate the mutual helicity of two coronal loops (see figure 3). For simplicity, let the corona be the upper half-space $\{z > 0\}$. The photospheric ($z = 0$) ends of the loops are assumed to be small and located at the points $\boldsymbol{x}_1^+, \boldsymbol{x}_1^-$ for loop 1 and $\boldsymbol{x}_2^+$, and $\boldsymbol{x}_2^-$ for loop 2. Here $B_z > 0$ at $\boldsymbol{x}_1^+$ and $\boldsymbol{x}_2^+$. Also, if the loops cross over each other when viewed from above, then let the upper loop be loop 1. Finally, let θ_{1+2-} be the angle of the line segment from $\boldsymbol{x}_1^+$ to $\boldsymbol{x}_2^-$, measured with respect to the x-axis.

Construct the field by first placing loop 2 in its present position, but with loop 1 at infinity. This configuration has zero mutual helicity. Next move loop 1 into place, using equation (6) to measure the helicity change. Because we are moving the upper loop, none of the angles change by more than π. The result is (ignoring the self-helicities due to twist)

$$K_{\mathcal{V}} = \frac{F_1F_2}{\pi}(\theta_{1+2-} + \theta_{1-2+} - \theta_{1+2+} - \theta_{1-2-}).$$

Addition of helicities

Suppose we divide space into two regions $\mathcal{V}_1$ and $\mathcal{V}_2$ with boundary S. For example, S could be the solar photosphere, with $\mathcal{V}_1$ the solar interior and $\mathcal{V}_2$ the corona. Let the magnetic field $\boldsymbol{B} = \boldsymbol{B}_1$ in $\mathcal{V}_1$ and $\boldsymbol{B} = \boldsymbol{B}_2$ in $\mathcal{V}_2$. We will notate this as $\boldsymbol{B} = [\boldsymbol{B}_1, \boldsymbol{B}_2]$. We wish to compare the helicity integrated over all space

$$K(\boldsymbol{B}) = K([\boldsymbol{B}_1, \boldsymbol{B}_2]) = \int \boldsymbol{A}\cdot\boldsymbol{B}\,\mathrm{d}V$$

with the helicities $K_{\mathcal{V}_1}$ and $K_{\mathcal{V}_2}$ of the regions $\mathcal{V}_1$ and $\mathcal{V}_2$.

The corresponding potential fields $\mathcal{V}_1$ and $\mathcal{V}_2$ are $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$. One can show that

$$K_{\mathcal{V}_1} = K([\boldsymbol{B}_1, \boldsymbol{B}_2]) - K([\boldsymbol{P}_1, \boldsymbol{B}_2]). \qquad (7)$$

Thus $K_{\mathcal{V}_1}$ represents the helicity K of all space measured relative to that of the field with zero current in $\mathcal{V}_1$, i.e. $K([\boldsymbol{P}_1, \boldsymbol{B}_2])$. As $K_{\mathcal{V}_1}$ can also be calculated using equation (3), which only integrates over $\mathcal{V}_1$, $K_{\mathcal{V}_1}$ is independent of the exterior field $\boldsymbol{B}_2$.

Similarly, we may calculate $K_{\mathcal{V}_2}$ as

$$K_{\mathcal{V}_2} = K([\boldsymbol{P}_1, \boldsymbol{B}_2]) - K([\boldsymbol{P}_1, \boldsymbol{P}_2]) \qquad (8)$$

where we have exercised our freedom to choose the exterior field to be $\boldsymbol{P}_1$ without changing the result. Summing equations (7) and (8) gives us the addition formula

$$K_{\mathcal{V}_1} + K_{\mathcal{V}_2} = K([\boldsymbol{B}_1, \boldsymbol{B}_2]) - K([\boldsymbol{P}_1, \boldsymbol{P}_2]).$$

Note that the field $[\boldsymbol{P}_1, \boldsymbol{P}_2]$ is not potential; it has surface currents on S. The last term always vanishes when the boundary S is a plane or a sphere.

Magnetic Reconnection

Magnetic reconnection is a fundamental dynamical process in highly conductive plasmas. It can be regarded as the process that removes the following difficulty. On typical dynamical time scales a sufficiently hot spatially extended PLASMA behaves approximately as an ideal fluid in the sense that resistive effects are ignorable. As a consequence, the magnetic field is 'frozen' to the plasma motion and magnetic topology is conserved. This sets strong limitations on the accessible dynamical states. Large-scale magnetic flux tubes, which are strongly stretched out by the plasma pressure, as for instance observed in PLANETARY MAGNETOSPHERES or in stellar CORONAS, would be unable to release large amounts of their energy and return to a correspondingly relaxed state, as long as the plasma is trapped in the flux tubes. In other words, efficient transformation of magnetic to kinetic energy would largely be ruled out in ideal plasmas. There would be no obvious process that could counteract the generation of magnetic flux by dynamo processes and the magnetic fields in many space and astrophysical situations would grow secularly. Also, plasmas with magnetic fields of different origin would not be able to mix. Beginning in the late 1950s, several authors, including P A Sweet, E N Parker, H E Petschek and J W Dungey, introduced magnetic reconnection as the central process allowing for efficient magnetic to kinetic energy conversion in SOLAR FLARES and for interaction between the magnetized interplanetary medium and the MAGNETOSPHERE OF EARTH.

How does reconnection circumvent the difficulty associated with frozen-in magnetic fields? Resistive dissipation is more effective the more the electric current is localized to regions with a small spatial scale length. Thus, in reconnection a small-scale structure is generated in some region, such that there the constraint of ideal dynamics is broken. The interesting aspect is that a *local* non-ideality can have a *global* effect. Under such circumstances highly conducting plasma structures are able to transform magnetic to kinetic energy in an efficient way and the magnetic topology can change. According to a major line of present thinking, this is what happens in solar flares or magnetospheric substorms, and possibly in many other plasma processes in the universe.

Basic model

The formal description of reconnection requires the choice of a dynamical model. Here we confine the discussion to magnetohydrodynamics, where we allow for a finite resistivity (resistive MHD or 'RMHD') as the only non-ideal transport process. The corresponding basic equations consist of a combination of fluid dynamics and electrodynamics:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0 \tag{1}$$

$$\rho \frac{\partial \boldsymbol{v}}{\partial t} + \rho \boldsymbol{v} \cdot \nabla \boldsymbol{v} = -\nabla p + \boldsymbol{j} \times \boldsymbol{B} \tag{2}$$

$$\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B} = \boldsymbol{j}/\sigma \tag{3}$$

$$\frac{\partial e}{\partial t} + \nabla \cdot (e\boldsymbol{v}) = -p \nabla \cdot \boldsymbol{v} + j^2/\sigma \tag{4}$$

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} \tag{5}$$

$$\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{j} \tag{6}$$

$$\nabla \cdot \boldsymbol{B} = 0. \tag{7}$$

Here, ρ, $\boldsymbol{v}$, p, $\boldsymbol{j}$, $\boldsymbol{B}$, $\boldsymbol{E}$, σ^{-1}, e and μ_0 denote respectively mass density, velocity, pressure, current density, magnetic field, electric field, resistivity, plasma energy density and vacuum permeability (see the article on MAGNETOHYDRODYNAMICS). Here we mention only the fact that the equations (1)–(7) imply the conservation of energy. The balance of mechanical and electromagnetic energy, respectively, take the form

$$\frac{\partial}{\partial t}\left(\frac{\rho v^2}{2} + u\right) + \nabla \cdot \left(\left(\frac{\rho v^2}{2} + u + p\right)\boldsymbol{v}\right) = \boldsymbol{j} \cdot \boldsymbol{E} \tag{8}$$

$$\frac{\partial}{\partial t}\left(\frac{B^2}{2\mu_0}\right) + \nabla \cdot \left(\frac{1}{\mu_0}\boldsymbol{E} \times \boldsymbol{B}\right) = -\boldsymbol{j} \cdot \boldsymbol{E}. \tag{9}$$

Adding these two equations gives conservation of energy

$$\frac{\partial}{\partial t}\left(\frac{\rho v^2}{2} + u + \frac{B^2}{2\mu_0}\right) + \nabla \cdot \left(\frac{\rho v^2}{2}\boldsymbol{v} + (u + p)\boldsymbol{v} + \frac{1}{\mu_0}\boldsymbol{E} \times \boldsymbol{B}\right) = 0. \tag{10}$$

For some purposes it has proved useful to impose the condition of incompressibility on the flow velocity

$$\nabla \cdot \boldsymbol{v} = 0 \tag{11}$$

replacing (4). This simplifies the problem significantly. It should, however, be kept in mind that for an incompressible flow, an energy conservation law of the form of (10) is not available. However, mass conservation and momentum balance are still described appropriately.

In a resistive fluid the importance of resistivity is measured by the Lundquist number

$$S = \frac{v_A L}{\eta} \tag{12}$$

where $v_A = B/\sqrt{\mu_0 \rho}$ is the Alfvén velocity, $\eta = (\mu_0 \sigma)^{-1}$ the magnetic diffusivity and L a typical (global) scale length. Alternatively, one uses the magnetic reynolds number $R_m = vL/\eta$, where the Alfvén velocity is replaced by a typical plasma velocity v. (In the literature the expression 'magnetic Reynolds number' frequently is also used for the quantity S.) Large values of S or R_m, which are typical for space and astrophysical plasmas, correspond to small resistive effects. In the limit of large S or R_m, the terms involving resistivity can be neglected (unless singularities form) and equations (1)–(7) reduce to the equations of ideal magnetohydrodynamics (IMHD).

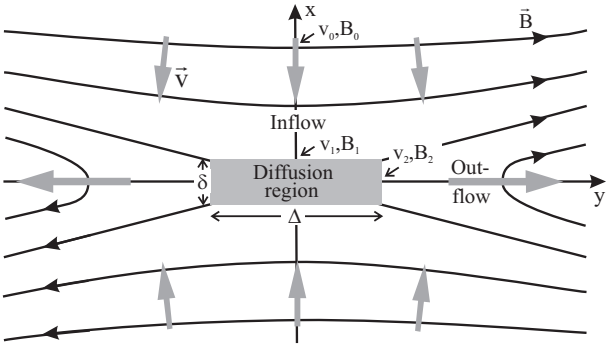

Figure 1. Qualitative pattern of two-dimensional reconnection.

Importantly, IMHD implies conservation of magnetic field line topology. In IMHD this fact can also be expressed by the property that two plasma elements that are connected by a magnetic field line at one time are connected by a magnetic field line at any later time (magnetic line conservation). Furthermore, the magnetic flux through an arbitrary contour transported by the plasma velocity field is also conserved. These properties provide the quantitative background for the dynamical constraints of IMHD mentioned above. In particular, they imply that large-scale topological reconfigurations of the magnetic field structure, as assumed to be associated with stellar and magnetospheric activity, are ruled out. In the following, we summarize in what sense magnetic reconnection resolves that dilemma and what is known at present about that process.

Two-dimensional reconnection

The simplest geometry in which reconnection may be described has two spatial dimensions, requiring the presence of an ignorable coordinate in three-dimensional physical space. In this section Cartesian coordinates x, y, z are used and it is assumed that the physical quantities are independent of z. We will first consider steady states and then introduce time dependence.

Steady-state reconnection

The basic configuration of two-dimensional steady-state reconnection is shown in figure 1. All field quantities are independent of time. Also, the magnetic field $\boldsymbol{B}$ and the plasma velocity $\boldsymbol{v}$ are assumed to lie in the x, y-plane, while for the electric field a non-vanishing z-component is admitted. The plasma is highly ideal such that the Lundquist number S (12) is much larger than 1.

To obtain an efficient conversion of magnetic to kinetic energy (along the trajectories of fluid elements) it is appropriate to assume a stagnation-type flow field $\boldsymbol{v}$ and oppositely directed magnetic fields in the upper and lower part of the inflow region (figure 1). The magnetic field vanishes at the origin (neutral point); viewed three-dimensionally a neutral line (line on which $B = 0$) extends along the z-axis.

Since S is large, for a smooth plasma flow with maximum gradients associated with the global length scale L the frozen-in condition would not allow annihilation of magnetic flux to any significant extent. This difficulty is avoided by the presence of a 'diffusion region' near the neutral line, where the resistive term j/σ in Ohm's law is much larger than in the approximately ideal environment ('external region'), typically by an enhancement of j_z. The diffusion region has length scales δ and Δ (figure 1) with $L \geq \Delta \geq \delta$. A locally defined Lundquist number, where L is replaced by δ in (12) can be considerably smaller than the global Lundquist number, indicating that in the diffusion region resistive diffusion can play an important role. There, the plasma and magnetic fields may decouple effectively, so that field annihilation along the fluid path becomes possible.

Under the present conditions (5) implies that E_z is a positive constant, say E_0. The presence of the diffusion region allows for a non-vanishing value of E_0, because otherwise (i.e. under ideal conditions with $\boldsymbol{j}/\sigma$ negligible) the z-component of equation (3) would require $E_z = 0$ at the neutral point, such that E_0 would have to vanish.

Another important property of the present geometry (shown in figure 1) is that $\partial B_y/\partial x > \partial B_x/\partial y$ or $j_z > 0$. Therefore, $\boldsymbol{E} \cdot \boldsymbol{j} = E_0 j_z > 0$ holds, which by (8) or (9) implies that magnetic energy is converted to kinetic energy. In fact, from (8) one finds

$$\frac{\partial}{\partial s}\left(\frac{v^2}{2} + \frac{u+p}{\rho}\right) > 0 \tag{13}$$

where (1) was used assuming that $\rho v \neq 0$, and s denotes the arc length of the trajectory of the plasma element (increasing in the direction of $\boldsymbol{v}$). Note that the thermal part on the left-hand side of (13) is enthalpy per unit mass rather than internal energy per unit mass, because the work done by the pressure force is included.

For a discussion of the consequences of mass and momentum conservation we specialize the resistive MHD equations (1)–(7) further, using the incompressibility condition (11) with constant density ρ_0 instead of (4). Then the resistive RMHD equations for a steady state assume the form

$$\rho \boldsymbol{v} \cdot \nabla \boldsymbol{v} = -\nabla p + \boldsymbol{j} \times \boldsymbol{B} \tag{14}$$

$$E_0 + \boldsymbol{v} \times \boldsymbol{B} \cdot \boldsymbol{e}_z = j_z/\sigma \tag{15}$$

$$\nabla \cdot \boldsymbol{v} = 0 \tag{16}$$

$$(\nabla \times \boldsymbol{B}) \cdot \boldsymbol{e}_z = \mu_0 j_z \tag{17}$$

$$\nabla \cdot \boldsymbol{B} = 0. \tag{18}$$

Quantities in the outer inflow region will be characterized by their magnitudes at the point $(x_0, 0)$ where the positive x-axis crosses the boundary, and are labeled by the subscript zero, in particular (in addition to ρ_0, E_0)

$$p_0 = p(x_0, 0), \quad B_0 = B_y(x_0, 0), \quad v_0 = -v_x(x_0, 0)$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(v_0 and B_0 are indicated in figure 1). Analogously, the subscripts '1' and '2' refer to the center inflow and outflow points on the boundary of the diffusion region (figure 1) and the subscript 'nl' is used for quantities on the neutral line.

Keeping the shape of the boundary fixed, except for the global scale length L, it can be expected that under the present conditions ρ_0, p_0, v_0, B_0, L and σ is a set of control parameters. Note, however, that in view of the nonlinearity of the problem a solution is not guaranteed for arbitrary parameter choices.

To disregard configurations that are merely the result of a similarity transformation, it is of interest to note that from these parameters three independent dimensionless quantities may be formed, which are conveniently chosen as

$$M_0 = \frac{v_0}{a_0}, \quad S_0 = \frac{a_0 L}{\eta}, \quad \beta_0 = \frac{2\mu_0 p_0}{{B_0}^2} \tag{19}$$

where a_0 is the (inflow) Alfvén velocity $B_0/\sqrt{\mu_0\rho_0}$. The earlier discussion of steady-state reconnection in the literature largely ignores the parameter β_0. This seems justified if β_0 is negligibly small or if pressure is constant in the external region. (It is only the gradient of the pressure that counts.) Then, reconnection is a two-parameter process, for instance described by M_0 and S_0. The parameter M_0 is regarded as of particular interest and is usually called reconnection rate. It measures the velocity with which the plasma enters the region of consideration (normalized by the local Alfvén velocity). The so-defined reconnection rate should not be confused with the rate of magnetic flux reconnection, which is defined by the rate at which flux conservation is violated in the reconnection process, which, in the present case, is given by the electric field component E_z along the neutral line, which equals $E_0 = v_0 B_0$.

There is no fully satisfactory analytical treatment of the system of equations (14)–(18). There are solutions for the external (ideal) region and solutions for the diffusion region, based on singular asymptotic expansions. However, a rigorous matching of such solutions has not yet been achieved. In this situation one introduces intuitive assumptions or simplifications. Much of the discussion in the literature is based on the following approximate picture.

Consistent with $j_z > 0$, let us assume that the aspect ratio $\kappa = \Delta/\delta$ is large compared to 1, that derivatives with respect to x are large compared with derivatives with respect to y and that $|B_x| \ll B_0$. Pressure is treated as constant in the external region. Then approximate relations are obtained in the following way:

Condition of incompressibility (11):

$$v_1 \Delta = v_2 \delta.$$

x-component of momentum balance (14) at $y = 0$:

$$p_1 + \frac{{B_1}^2}{2\mu_0} = p_{\rm nl}.$$

y-component of momentum balance at $x = 0$, ignoring B_x:

$$\frac{\rho_2 {v_2}^2}{2} + p_2 = p_{\rm nl}.$$

Ohm's law:

$$E_0 = v_1 B_1 = v_2 B_2 = j_{\rm nl}/\sigma.$$

Ampère's law (6) (replacing the derivative by a difference quotient)

$$j_{\rm nl} = \frac{B_1}{\mu_0 \delta}.$$

Combining these equations and using that, in view of the assumptions, $\rho_2 = \rho_1 = \rho_0$, $p_1 = p_2 = p_0$ one obtains

$$v_2 = a_1 \tag{20}$$

$$M_1 = \frac{1}{\kappa} = \frac{1}{\sqrt{S_1}} \tag{21}$$

$$\frac{M_1}{M_0} = \left(\frac{B_0}{B_1}\right)^2 \tag{22}$$

$$\frac{\Delta}{L} = \frac{S_1 B_0}{S_0 B_1}. \tag{23}$$

This system of equations has to be completed by an equation for the ratio B_0/B_1 which requires a more complete solution of equations (14)–(18). In the absence of such a solution one introduces an additional condition as an *ad hoc* assumption, or from the external solution alone, or on the basis of numerical computations. We give three examples.

(a) Sweet–Parker model. Here it is assumed that the diffusion region is a thin extended structure such that Δ becomes of the order of L. For simplicity, let us set $\Delta = L$. The external region is largely homogeneous such that approximately $B_1 = B_0$ and $S_1 = S_0$. Under these conditions, (21) gives the reconnection rate as

$$M_0 = \frac{1}{\sqrt{S_0}}.$$

This rate is generally regarded as too low to be relevant for typical conditions in stellar atmospheres and space plasmas because of their large Lundquist numbers.

(b) Petschek's model. In this model it is assumed that $\Delta \ll L$. In that case, it is necessary to consider the presence of slow-mode shock waves (here in the limit of incompressibility) which implies that B_1 may be considerably smaller than B_0. Approximately, one finds $B_1/B_0 = 1 - 4M_0/(\pi \ln(R_{m_0}))$. The maximum reconnection rate occurs near $B_1/B_0 = 1/2$, such that

$$M_0 < \frac{\pi}{8}\frac{1}{\ln R_{m_0}}.$$

Typically this reconnection rate is considerably larger than that of the Sweet–Parker process.

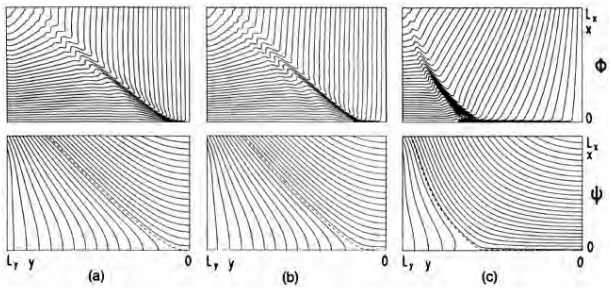

Figure 2. Numerical solutions of equations (25) and (26) with $\Psi = \hat{A}$ and $\Phi = \hat{D}$ by Biskamp. In (*b*) and (*c*) the Lundquist number of (*a*) is increased by factors of 2 and 4, respectively (from Biskamp 1986).

(c) Further reconnection models. Several authors (e.g. W I Axford, B U Ö Sonnerup, E R Priest, T G Forbes) have generalized the models by Sweet and Parker and by Petschek in various respects. The most general are the fast reconnection models of Priest and Forbes. They included electrical currents in the external region and obtained a description that contains the Sweet–Parker and Petschek models as particular cases.

For numerical studies (as for other purposes) it is convenient to represent $\boldsymbol{v}$ and $\boldsymbol{B}$ by single flux functions $D(x, y)$ and $A(x, y)$. This is possible because of the vanishing divergence of both fields and the absence of z-components,

$$\boldsymbol{B} = \nabla A \times \boldsymbol{e}_z, \quad \boldsymbol{v} = \nabla D \times \boldsymbol{e}_z. \tag{24}$$

Then, one eliminates the electric current density by using (17), and the pressure by taking the curl of the momentum equation. The remaining equations of the system (14)–(18) are usually written in non-dimensional form (here non-dimensional quantities carry the hat-label), such that A is normalized by $B_0 L$, the velocity potential D by $a_0 L$ and coordinates by L

$$[\Delta \hat{D}, \hat{D}] = [\Delta \hat{A}, \hat{A}] \tag{25}$$

$$M - [\hat{A}, \hat{D}] = -\frac{1}{S_0} \Delta \hat{A}. \tag{26}$$

For functions $f(x, y)$, $g(x, y)$ the symbol $[f, g]$ is defined by

$$[f, g] = \frac{\partial f}{\partial x}\frac{\partial g}{\partial y} - \frac{\partial f}{\partial y}\frac{\partial g}{\partial x}.$$

Equations (25) and (26) have been solved numerically for a variety of boundary conditions by several groups. Figure 2 shows, for example, a result by Biskamp, demonstrating that a Sweet–Parker current sheet rapidly develops for increasing S_0.

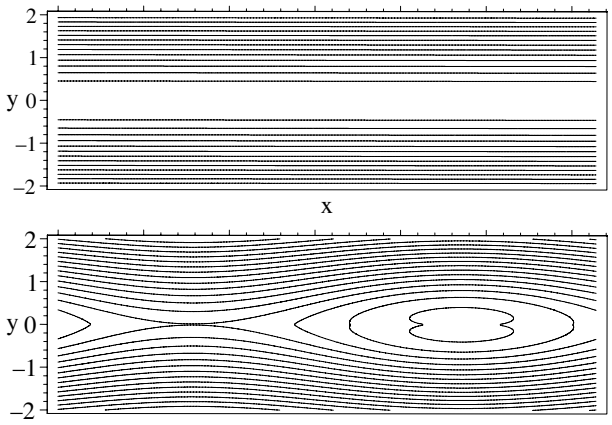

Figure 3. Magnetic field lines of the unperturbed Harris sheet (upper panel) and the linear tearing mode (lower panel).

Time-dependent reconnection

Although, historically, steady-state reconnection has been given great deal of attention, it seems that in many cases magnetic reconnection occurs as a time-dependent process. Several features of steady-state reconnection are also present in typical time-dependent (two-dimensional) cases, such as a neutral line and an associated stagnation-flow pattern. This analogy is particularly close for driven reconnection, where—as in steady states—the plasma inflow is determined by boundary conditions.

A qualitatively different case arises when reconnection occurs as an unstable process. The prototype of an instability involving reconnection is the tearing mode (suggested by H P Furth, J Killeen and M N Rosenbluth). A plane current sheet located in an infinite domain undergoes spontaneous formation of magnetic islands (figure 3). Resistivity plays a similar role as in steady states: it is important only in regions of strong current concentration. Assuming that the unperturbed configuration does not involve such concentrations, it can be described in the limit of $S \to \infty$. The classical example is the Harris sheet, where the unperturbed magnetic field $\boldsymbol{B}$, the flux function A and the plasma pressure p are given (in dimensionless form) by

$$\boldsymbol{B} = -\tanh(x)\boldsymbol{e}_y, \quad A = \ln(\cosh(x)), \quad p = \frac{1}{\cosh^2(x)}$$

which is a static solution of (25) and (26) for infinite S.

The instability generates the required current concentration spontaneously. The dynamical evolution is described by equations (25) and (26), if generalized to include time dependence. In view of the time dependence, it is appropriate to derive the electric field from the time dependence of the flux function A, rather than from an electric potential. In dimensionless form one obtains the following linearized equations for the perturbations ϕ and ψ of the velocity potential D and the flux function A

$$\Delta \frac{\partial \psi}{\partial t} = [\Delta a, A] + [\Delta A, a] \tag{27}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\frac{\partial a}{\partial t} = \frac{1}{S}\Delta a - [A, \psi]. \tag{28}$$

Choosing modes of the form

$$\psi(x, y, t) = \hat{\psi}(y)\, \mathrm{e}^{\mathrm{i}\alpha y + qt}$$

with a corresponding expression for ϕ, (27) and (28) give two ordinary differential equations for $\hat{\psi}$ and $\hat{\phi}$. These equations are solved analytically by a singular perturbation method for the regime

$$\frac{1}{S} \ll |q| \ll 1, \quad |q^2| \ll \alpha^2 < 1.$$

The essential aspect is the occurrence of a thin region around $y = 0$ of width $\epsilon = (q/(\alpha^2 S))^{1/4}$, where the current density becomes large. Using appropriate scaling in this region and in the external region, one finds explicit solutions to lowest significant order in ϵ. The matching condition determines the dispersion relation, i.e. q as a function of α

$$\hat{q} = \frac{\sqrt{\lambda}}{\pi} \frac{\Gamma\left(\frac{\lambda+1}{4}\right)}{\Gamma\left(\frac{\lambda+3}{4}\right)} (1 - \alpha^2)(1 - \lambda^2)$$

where

$$\lambda = \frac{\hat{q}^{3/2}}{\hat{\alpha}}, \quad \hat{q} = qS^{1/2}, \quad \hat{\alpha} = \alpha S^{1/4}.$$

The tearing mode develops a series of magnetic islands with corresponding X-type and O-type neutral lines (figure 3). The local structure near the X-line resembles the steady-state reconnection pattern of figure 1.

For the reconnection processes associated with solar flares and magnetospheric substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS) more realistic two- and three-dimensional models have been developed (pioneered by J Birn, A Otto, T G Forbes, Z Mikic and others). Figure 3 gives a qualitative sketch of the magnetic field structure as it develops with time. The original equilibrium configuration becomes unstable by a process which is a generalization of the tearing mode shown in figure 3. During its nonlinear evolution a plasmoid forms, which grows, becomes accelerated and eventually leaves the system, carrying a substantial amount of energy that was stored in the original equilibrium. Processes of this kind have been suggested to be relevant for magnetospheric substorms, solar flares and SOLAR CORONAL MASS EJECTIONS. For the magnetosphere it is believed that the onset of the non-ideal (e.g. resistive) process is related to the formation of a thin current sheet late in phase (a) in figure 4.

In the case of three-dimensional modeling one encounters new aspects, as compared with reconnection in two dimensions, which are discussed in the following section.

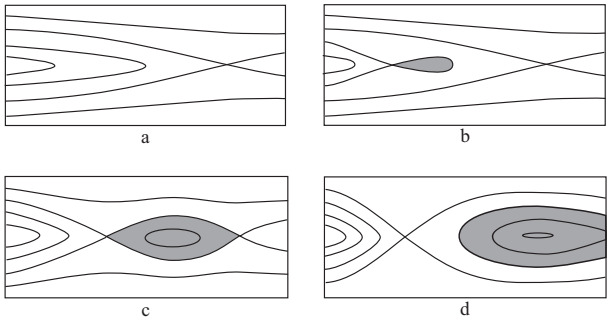

Figure 4. Plasmoid formation and ejection in a stretched magnetic field configuration.

Three-dimensional reconnection

The two-dimensional models discussed so far seem to be realistic for reconnection occurring in three-dimensional space only if the z-dependence is small and if the extent of the reconnection region along the perpendicular direction (z-direction) is large enough that effects of the edges can be neglected. Moreover, it requires that magnetic flux of exactly opposite direction is convected along the x-axis into the reconnection region. Each of these assumptions is doubtful, and so a generalization with a component of the magnetic field along the invariant direction is required which allows for magnetic flux to approach the reconnection region with a non-vanishing z-component. This is most simply realized by adding a constant B_z-component in the model given by equations (14)–(18). This requires an additional (E_x, E_y) component of the electric field, which has the form of a gradient ($\nabla(B_z D)$ for the representation of $\boldsymbol{v}$ given in equation (24)). It therefore does not destroy the stationarity of these models nor does it modify the momentum equation.

Although the additional B_z-component seems to be a minor modification, it gives rise to several fundamental questions about the notion of reconnection. In two dimensions ($B_z = 0$) reconnection is usually defined by the existence of an X-type neutral point and a flow of stagnation type which transports magnetic flux across the separatrices, i.e. the field lines which end at the neutral point and separate the magnetic flux of the inflow and outflow regions (see figure 1). With the additional B_z component, the former neutral line of the two-dimensional models now becomes an ordinary magnetic field line and the former separatrices, or separatrix surfaces, respectively, do not exist anymore or, if the notion of a separatrix is applied to the projection of the field onto the plane perpendicular to the field line, they are not unique. (The latter can be shown by the example $\boldsymbol{B} = (y, x, 1)$, where every field line possesses separatrices in this sense, i.e. has an X-type magnetic field in the plane perpendicular to the field line.) These difficulties become even more serious for fully three-dimensional magnetic fields without translational invariance. Several methods have been proposed to solve these difficulties of localizing and defining reconnection.

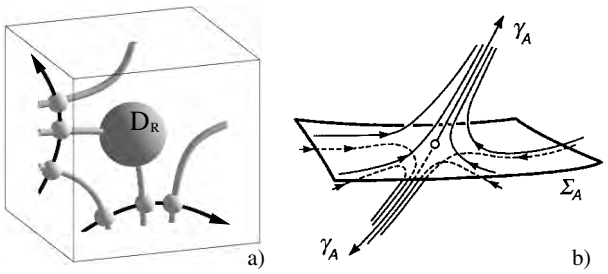

Figure 5. (*a*) Sketch of a breakdown of magnetic line conservation at a localized non-ideal region D_R. Two plasma elements (small spheres) which originally share a field line end up on different field lines. (*b*) Topology of field lines in the vicinity of an A-type generic null, showing the spine (γ_A) and the fan (Σ_A); B-type nulls have reversed field directions (from Lau and Finn 1990).

First, it is tempting to use the plasma flow in addition to the structure of the magnetic field to identify reconnection. However, this quantity is not independent of the frame of reference used, and for instance the location of the stagnation point depends on the observer. In another approach Hesse and Schindler therefore used the original meaning of reconnection, i.e. a breakdown of magnetic field line conservation (first suggested by Axford). They introduced the notion of general magnetic reconnection to occur if

$$\int \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s} \neq 0 \tag{29}$$

where the integral is evaluated for field lines passing through a localized non-ideal region D_R embedded in an otherwise ideal plasma (see figure 5). The criterion (29) is sufficient for a breakdown of magnetic line conservation, provided all magnetic field lines start and end in the ideal region outside D_R. This is a consequence of the general form of magnetic field line conservation

$$\frac{\partial \boldsymbol{B}}{\partial t} - \nabla \times (\boldsymbol{w} \times \boldsymbol{B}) = \lambda \boldsymbol{B} \tag{30}$$

where $\boldsymbol{w}$ is the transport velocity of the field lines, which can be identified with the plasma velocity $\boldsymbol{v}$ in the ideal region but may differ from it in non-ideal processes. Equation (30) implies $\boldsymbol{B} \cdot \nabla\lambda = 0$, and therefore λ is constant on magnetic field lines. Moreover, in the ideal region we have $\boldsymbol{w} = \boldsymbol{v}$ and $\lambda = 0$ and hence $\lambda = 0$ across D_R as well. In this case equation (30) together with the induction equation implies

$$\boldsymbol{E} + \boldsymbol{w} \times \boldsymbol{B} = \nabla\Psi \tag{31}$$

and therefore $\int \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s} = 0$ along all magnetic field lines, because $\nabla\Psi$ vanishes in the ideal region so that Ψ is constant outside D_R. A non-vanishing integral (equation (29)) therefore requires a breakdown of magnetic line conservation. Vice versa, if $\int \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s} = 0$ holds for all magnetic field lines crossing D_R, the potential Ψ can be integrated within D_R from

$$\boldsymbol{E} \cdot \boldsymbol{e}_B = \nabla\Psi \cdot \boldsymbol{e}_B \tag{32}$$

and the field line velocity, given by

$$\boldsymbol{w} = (\tilde{\boldsymbol{E}} \times \boldsymbol{B})/\boldsymbol{B}^2 \tag{33}$$

with $\tilde{\boldsymbol{E}} = \boldsymbol{E} - \nabla\Psi$, exists provided there is no magnetic null within D_R. In this case (29) is also necessary for a breakdown of magnetic line conservation.

Magnetic null points

The existence of $\boldsymbol{w}$ given by (33) is critical if there are magnetic nulls within D_R. Using $\boldsymbol{E} = -\nabla\varphi - \frac{\partial \boldsymbol{A}}{\partial t}$ for a given evolution of an electromagnetic field, (32) can be restated by the existence of a potential $\tilde{\varphi} = \varphi + \Psi$ with

$$\boldsymbol{B} \cdot \nabla\tilde{\varphi} = -\boldsymbol{B} \cdot \frac{\partial \boldsymbol{A}}{\partial t} \tag{34}$$

where $\boldsymbol{A}$ is a vector potential for $\boldsymbol{B}$. Given the potential $\tilde{\varphi}$ on a surface crossed only by non-recurring field lines this condition defines $\tilde{\varphi}$ along these field lines. This method, called potential mapping, does not necessarily lead to a smooth potential $\tilde{\varphi}$ if field lines from separated regions join at magnetic nulls. For instance, smooth boundary conditions on $\tilde{\varphi}$ given for all field lines entering a surface enclosing the null, may lead to discontinuities of $\tilde{\varphi}$, and if the boundary is part of the ideal region the condition on $\tilde{\varphi}$ corresponds to boundary conditions on the plasma velocity $\boldsymbol{v}$. Therefore, Greene, followed by Lau and Finn, argued that in an almost-ideal plasma magnetic nulls are the site where non-ideal terms, especially the resistive term in Ohm's law, become important, and hence a breakdown of magnetic field line conservation may take place.

Magnetic nulls can be classified in terms of the eigenvalues of the tensor $\nabla\boldsymbol{B}$. They have either one real and two complex conjugated eigenvalues or three real eigenvalues. For the latter case they are called type A for $(+\,-\,-)$ signs of the eigenvalues and type B for $(-\,+\,+)$ (see figure 5). The eigenvectors of the complex conjugated eigenvalues, or of the real eigenvalues with the same sign, span a magnetic surface called the *fan* surface by Priest and Titov. The third eigenvector defines the spine as shown in figure 5. In the the case of more than one magnetic null the fan surfaces of an A-type and B-type null intersect at a structurally stable magnetic field line called separator. It can be shown that this field line is also a potential site of reconnection due to discontinuities in $\tilde{\varphi}$ or singularities of $\boldsymbol{w}$ for corresponding boundary conditions.

The topological structure of magnetic nulls led Priest and Titov to propose two additional mechanisms of reconnection called spine and fan reconnection. They showed that certain prescribed motions of the field lines on a surface enclosing the null produce singular field line velocities according to equation (33), and hence require a breakdown of field line conservation. In spine and fan reconnection the current tends to concentrate along the the spine and fan respectively.

Reconnection without nulls

Magnetic nulls are not the only places where magnetic reconnection may occur. For instance if equation (34) is integrated over a closed field line with a non-vanishing contribution of the right-hand side, one finds that the potential $\tilde{\varphi}$ may not exist and therefore processes breaking the magnetic line conservation have to be present. This is also reflected by the criterion (29) which does not require nulls. For a non-vanishing magnetic field the method of potential mapping always leads to a smooth potential $\tilde{\varphi}$ and transport velocity $\boldsymbol{w}$. However, the latter might be very large, much higher than the Alfvén velocity, which excludes under realistic conditions an ideal evolution. This may happen, as noted by Priest, Forbes and Demoulin, in layer-like regions where the potential mapping or mapping of foot points of field lines shows strong gradients and which are therefore called magnetic flipping layers or quasi-separatrix layers.

While the method of potential or field line mapping aims at finding potential sites of reconnection and thus adds to the general criterion (29) certain conditions on the structure of the magnetic field, Hornig gave a more restricted definition of reconnection by generalizing the observation that in two dimension the field line velocity $\boldsymbol{w}$ has a singularity at the X-point. A covariant description shows that this singularity is a special type of null of the corresponding four-vector field W^4. This property is structurally stable in the transition from two to three dimensions, where now the site of reconnection is determined by a line of finite length along which W^4 vanishes. Within this definition it is in particular possible to distinguish a simple local slippage of plasma relative to the field lines, which also may satisfy (29) but which is not usually called reconnection, from reconnection itself.

Another aspect of reconnection is the dynamics of MAGNETIC HELICITY. While in two dimensions the source of magnetic helicity ($-2\boldsymbol{E}\cdot\boldsymbol{B}$) vanishes, this is not necessarily the case in three dimensions. Hence magnetic reconnection in three dimensions does not necessarily conserve magnetic helicity.

Collisionless reconnection

Magnetic reconnection can also occur in the absence of a collisional resistivity. Collisionless reconnection processes are based on non-ideal terms that in a more refined macroscopic picture appear on the right-hand side of Ohm's law (3) in addition to the resistive term. For instance, a current-driven microinstability may lead to fluctuations that on the macroscopic level have an effect similar to resistivity based on particle collisions. Also, resonant wave–particle interaction, off-diagonal terms of the electron pressure tensor or electron inertia have been suggested for magnetic reconnection. The final assessment of the role that each of these processes plays in reconnection requires a full three-dimensional kinetic description. Although such a kinetic point of view is crucial for the understanding of the small-scale plasma physics of reconnection, it less crucial for the overall dynamics, which in many of its features seems to be largely independent of the type and details of the non-ideal process. Thus, even highly collisionless reconnection processes, as for instance occurring in the Earth's magnetosphere, have been successfully simulated by using a simple resistive model of the form (3). Often, the resistivity is empirically adapted, for instance by spatial localization or by introducing an *ad hoc* dependence of η on the electric current density. The formation of thin current sheets in the pre-reconnection dynamics seems to play an important role in the onset of collisionless reconnection processes.

Magnetohydrodynamic Instabilities

Magnetohydrodynamic (MHD) stability theory determines whether a given PLASMA equilibrium configuration will either remain unchanged or evolve dynamically, in response to a general initial disturbance. If there is an initial disturbance whose amplitude subsequently grows in time, then the plasma is unstable, otherwise the plasma is stable. In addition, if the initial destabilizing disturbance has a small amplitude (normally referred to as infinitesimally small), then the plasma is linearly unstable and linear theory is appropriate. However, if the initial amplitude has a finite magnitude, then it is nonlinearly unstable. In many physical applications the plasma switches from a stable configuration to an unstable one as some parameter or property of the equilibrium exceeds a critical value. When the critical value is reached, the plasma is at marginal stability.

Many of the various solar phenomena can be understood by considering the typical timescales of the various physical processes in the solar CORONA. This is shown in table 1 and discussed in the subsequent sections.

Table 1. Typical timescales, in seconds, for the physical processes in the solar corona assuming $B = 100$ G, $l = 5 \times 10^7$ m, $\rho = 8.36 \times 10^{-13}$ kg m^{-3} and $T = 2 \times 10^6$ K. R is the gas constant.

Physical process	Symbol	Definition	Timescale (s)
Alfvén	τ_A	$l\sqrt{\mu\rho}/B$	5
Sound	τ_s	$l/\sqrt{RT}$	200
Conduction	$\tau_{\rm cond}$	$pl^2/\kappa_\parallel T$	600
Radiation	$\tau_{\rm rad}$	$p/\rho^2 Q(T)$	3000
Diffusion	τ_d	l^2/η	2.5×10^{15}

In this article a brief description of the equilibrium state is presented, followed by an introduction to the various methods used to assess the stability properties of the plasma. Next we describe ideal and non-ideal MHD instabilities before discussing some particular effects of coronal magnetic fields that penetrate the dense SOLAR PHOTOSPHERE.

MHD equilibrium

The basic MHD equilibrium equations are

$$\nabla p = \boldsymbol{j} \times \boldsymbol{B} + \rho \boldsymbol{g} \tag{1}$$

for magnetic equilibrium. A non-uniform magnetic field, i.e. $\boldsymbol{j} \neq 0$, can create current driven instabilities such as the MHD kink instability. An adverse density profile and the gravity term can drive Rayleigh–Taylor modes and the pressure gradient can drive localized modes. In addition to the force balance equation (1), the equilibrium magnetic field and plasma must satisfy

$$\nabla \cdot \boldsymbol{B} = 0 \qquad \boldsymbol{j} = \frac{1}{\mu} \nabla \times \boldsymbol{B} \tag{2}$$

and an energy equation. For most situations this is taken as the adiabatic energy equation with

$$p = \text{const}\ \rho^\gamma .$$

For thermal instabilities a more appropriate energy equation, instead of the adiabatic equation, must be used, including thermal conduction, optically thin radiation ($\rho^2 Q(T)$) and some form of coronal heating. Hence, thermal equilibrium is described by

$$\nabla \cdot (\kappa \nabla T) = L(p, T) \equiv \rho^2 Q(T) - H. \tag{3}$$

κ is the thermal conductivity tensor, but in a magnetized plasma this is dominated by the component parallel to the magnetic field, $\kappa_\parallel$. It has a strong temperature dependence and is expressed as $\kappa_\parallel = 10^{-11} T^{5/2}$ W m^{-1} K^{-1}. L is the total loss function, including the coronal heating term, H, and $Q(T)$ is normally approximated by a piecewise continuous function of the form

$$Q(T) = \chi T^\alpha$$

where χ and α are constants dependent on the temperature. These are given in table 2. Finally, the temperature is coupled to the pressure and density through the gas law

$$p = \rho \mathcal{R} T$$

where $\mathcal{R}$ is the gas constant.

Table 2. The constants used in the radiative loss function $Q(T) = \chi T^\alpha$ W m^{-3} kg^{-2}. (From Cook *et al* (1989).)

T	χ	α
$T > 10^{6.5}$	7.15×10^{17}	0
$10^6 < T < 10^{6.5}$	1.25×10^{34}	−2.5
$10^5 < T < 10^6$	1.25×10^{19}	0
$10^4 < T < 10^5$	3.93×10^{13}	1.1

Stability methods

The energy method

The linear stability of a given equilibrium can be tested using three different methods. If it is important to know whether a plasma is either stable or unstable, an energy method (Bernstein *et al* 1954) can be used. The sign of the perturbed potential energy, δW, integrated over the volume of the plasma determines stability. δW is defined by

$$-\frac{1}{2} \int \xi \cdot \boldsymbol{F}(\xi)\, \mathrm{d}V \tag{4}$$

and

$$\begin{aligned} \delta W > 0 \text{ for all } \xi &\Rightarrow \text{stability} \\ \delta W < 0 \text{ for one allowable } \xi &\Rightarrow \text{instability.} \end{aligned} \tag{5}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$\boldsymbol{F}(\xi)$ is the linearized force given by

$$\begin{aligned}\boldsymbol{F}(\xi) = &\nabla(\xi \cdot \nabla p + \gamma p \nabla \cdot \xi) \\ &+ (\nabla \times \nabla \times (\xi \times \boldsymbol{B})) \times \boldsymbol{B}/\mu \\ &+ (\nabla \times \boldsymbol{B}) \times \nabla \times (\xi \times \boldsymbol{B})/\mu \\ &- \nabla \cdot (\rho\xi)\boldsymbol{g}. \end{aligned} \tag{6}$$

The displacement ξ must be continuous and satisfy the boundary conditions. The advantage of this method is that it is possible to prove instability by choosing a trial displacement that makes δW negative. This gives a necessary condition for stability. In addition, it is possible to rearrange the energy integral into two terms, one a positive definite term and the other a simpler integral. Minimizing this second integral and showing that it is positive gives a sufficient condition for stability. Thus, simple bounds on the stability threshold can be obtained.

The normal mode method

Assuming a time dependence of the form $e^{-i\omega t}$, the linearized MHD equations reduced to an eigenvalue problem of the form

$$-\omega^2 \xi = \boldsymbol{F}(\xi),$$

for the eigenvalue ω^2. If all values of ω^2 are positive then the plasma is stable but if there exists one $\omega^2 = -\sigma^2$ that is negative, then the plasma is unstable. Here ω is the frequency of oscillation of a stable wave and σ is the growth rate of an unstable mode. The spectrum of the system is complicated by the existence of a continuous spectrum for ω^2 as well as the discrete spectrum of modes.

The initial value method

A final approach is to treat the equations as an initial value problem and time advance the equations numerically. If the initial disturbance is sufficiently general, then the most unstable mode will grow and eventually dominate the solution. This approach is frequently used as a forerunner to a full nonlinear simulation. Whichever approach is used, it is important that a complete description of the linear stability properties of the equilibrium is obtained before detailed (and time-consuming) nonlinear calculations are carried out.

Rayleigh–Taylor instability

The Rayleigh–Taylor instability occurs when gravity interacts with an adverse density gradient. Imagine two plasmas of uniform densities ρ_1 in $z > 0$ (region 1) and ρ_2 in $z < 0$ (region 2), separated by an interface at $z = 0$. Using a normal mode analysis with disturbances of the form $f(x, z, t) = f(z)\, e^{i(\omega t - kx)}$, matching the two solutions in the separate regions, $z > 0$ and $z < 0$, and using continuity of both the normal velocity and the perturbed total pressure at the perturbed interface, the incompressible dispersion relation is obtained as

$$\omega^2 = kg\frac{\rho_2 - \rho_1}{\rho_2 + \rho_1}. \tag{7}$$

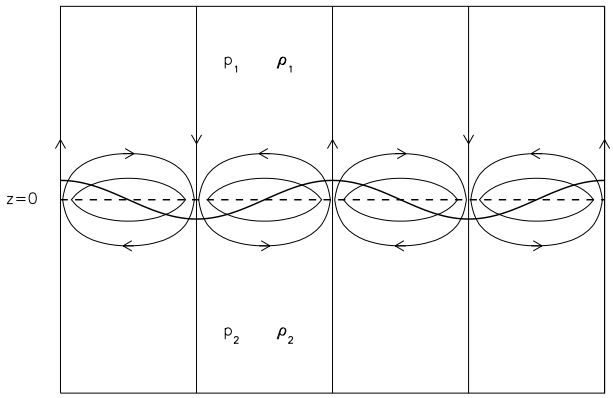

Figure 1. The streamlines for the Rayleigh–Taylor instability are shown. The unperturbed interface at $z = 0$ is shown as a thick dashed line and the perturbed interface as the thick full curve

Notice that the plasma is unstable when $\rho_1 > \rho_2$, i.e. heavy plasma overlies light, and that the fastest growing instability occurs for $k \to \infty$. Thus, the wavelengths are extremely small when the plasma is unstable. The form of the instability is shown in figure 1.

The inclusion of a uniform magnetic field at an angle θ to the x-direction modifies this result giving the dispersion relation as

$$\omega^2 = kg\frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} + \frac{2}{\mu}\frac{(kB\cos\theta)^2}{\rho_2 + \rho_1}. \tag{8}$$

The second term on the right-hand side represents the effect of magnetic tension that is introduced when the perturbation bends the fieldlines. When $\theta = 0$, then the magnetic field stabilizes the Rayleigh–Taylor mode if the wavenumber satisfies

$$k > \frac{g\mu}{2B^2}(\rho_1 - \rho_2). \tag{9}$$

Note that if $\theta = \pi/2$ so that

$$\boldsymbol{k} \cdot \boldsymbol{B} = kB\cos\theta = 0$$

the magnetic field does not influence the Rayleigh–Taylor mode at all. This condition appears in many stability criteria. Further information about gravitational instabilities is given in the article on MAGNETIC BUOYANCY.

Rayleigh–Taylor instabilities are expected whenever dense plasma overlies light plasma. A classic example of this type of situation occurs at the lower edge of a SOLAR PROMINENCE. Here the dense plasma is supported against gravity by the Lorentz force. There is normally a fairly clear lower edge to prominences so the Rayleigh–Taylor instability must be inhibited possibly by either magnetic shear or photospheric line-tying effects.

Magnetic instabilities

Magnetic instabilities are best described by the example of cylindrically symmetric magnetic fields. In this case, (1)

reduces to

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(p + \frac{B^2}{2\mu}\right) = -\frac{B_\theta^2}{\mu r} \tag{10}$$

where the azimuthal and axial components of the magnetic field are $B_\theta(r)$ and $B_z(r)$ respectively and the gas pressure is $p(r)$. The left-hand side is the total pressure gradient and the right-hand side is the magnetic tension. Since the equilibrium only depends on the radial coordinate, all perturbations can be Fourier analyzed in the form

$$f(\mathbf{r}, t) = f(r)\,\mathrm{e}^{\mathrm{i}(m\theta + kz - \omega t)} \tag{11}$$

and the linearized equations reduce to a set of ordinary differential equations.

Low-m, global modes

The nature of the mode is defined by the value of the azimuthal wavenumber m. $m = 0$ is the sausage mode and $m = 1$ is the kink mode. The form of these perturbations is shown in figure 2. In both cases the regions of strong magnetic field force the plasma towards the regions of weak magnetic field and so reinforce the plasma displacement. However, it is important to note that the kink mode instability is the only mode that actually displaces the magnetic axis.

The exponential term has constant amplitude along the helix defined by $m\theta + kz =$ constant. The pitch of the disturbance matches the pitch of the equilibrium magnetic field when

$$\boldsymbol{k} \cdot \boldsymbol{B} = \frac{m}{r} B_\theta + k B_z = 0. \tag{12}$$

This condition is satisfied at a particular radius, r_s, the radius of a mode rational surface, and corresponds to a singularity in the ideal MHD, marginal stability equations when $\omega^2 = 0$.

Inertial line-tying

The stability of solar coronal magnetic fields is strongly influenced by the effect of the very dense photosphere. Imagine an Alfvén wave propagating down from the corona. When it reaches the photospheric level there is a large increase in density of a factor of 10^8 and the wave is almost totally reflected. In a similar manner, a slow MHD WAVE is also reflected. The photosphere provides a strong stabilizing effect, called inertial line-tying, and the simplest way to model this is to assume that all components of the displacement (or equivalently the velocity) are zero at the photospheric ends of the fieldlines. This means that the wavenumber along the magnetic fieldline is not only discretized but, because the components of the displacement are out of phase with each other, also couples Fourier components together. An individual Fourier mode does not satisfy the boundary conditions and so many modes must be included.

In periodic configurations the first modes to become unstable are incompressible modes. This can be understood, since if some of the available energy is used in compressing the plasma then there is less to drive the instabilities. Thus, contracting the plasma as in figure 2(*a*) means that the plasma will flow towards the expanding regions, otherwise the plasma will be compressed. However, the line-tying conditions prevent this flow and so the most unstable line-tied plasma disturbances are usually compressible.

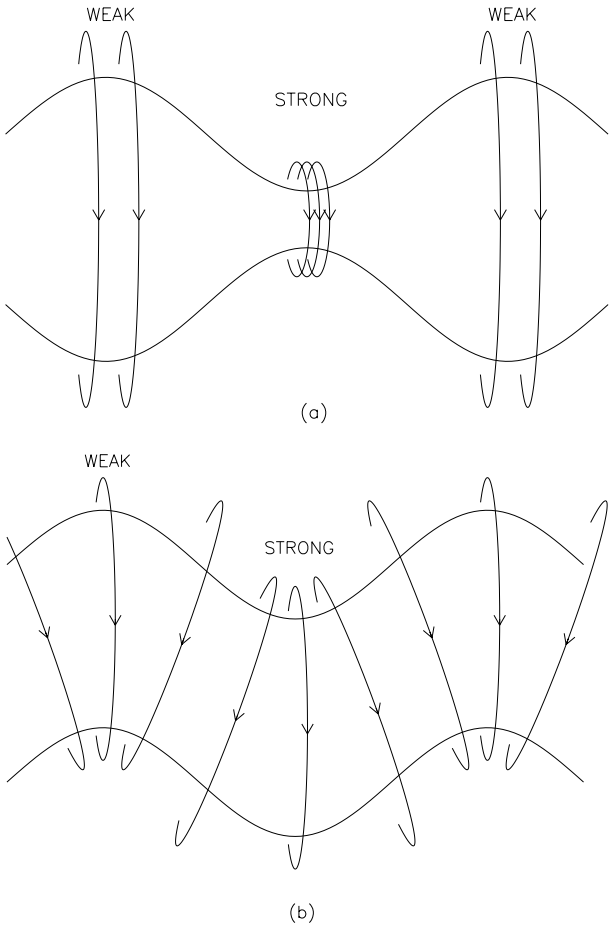

Figure 2. The displacements for (*a*) the sausage mode and (*b*) the kink mode.

High-m, localized modes

High m values for the azimuthal wavenumber produce modes that are strongly localized about a particular radius. These modes are driven by an adverse pressure gradient and are unstable, in the absence of line-tying, if Suydam's criterion holds, namely

$$\frac{B_z^2}{4}\left(\frac{q'}{q}\right)^2 + \frac{2\mu p'}{r} < 0 \tag{13}$$

where $q = r B_z / B_\theta$ gives a measure of the shear in the field. Line-tying modifies this result by adding two stabilizing effects due to field line tension and compression. The condition for instability is now

$$a_1 \frac{B_z^2}{4}\left(\frac{q'}{q}\right)^2 + a_2 \frac{2\mu p'}{r} + a_3 \frac{B^2}{r^2} + a_4 \frac{\gamma \mu p B_\theta^2}{\gamma \mu p + B^2} < 0 \tag{14}$$

where the constants, a_i, are defined in De Bruyne and Hood (1989).

Resistive instabilities

In ideal MHD the magnetic fieldlines are frozen into the plasma and hence retain their topological identity. However, once resistivity is included, fieldlines can diffuse through the plasma, allowing them to break and reconnect. Thus, new topological configurations can be accessed that were prohibited under ideal MHD. In cases where the new configurations have a lower magnetic energy, there are resistive instabilities that are driven by this available free magnetic energy. These new instabilities grow at a rate that is slower than the rates for ideal modes but faster than pure diffusion. In general, they have a growth rate that is related to a hybrid of the Alfvén and diffusion timescales, τ_A and τ_d as defined in table 1. The main resistive mode in the solar corona is the tearing mode with a growth rate

$$\sigma \propto \tau_A^{-2/5} \tau_d^{-3/5}. \tag{15}$$

The resistive modes are localized about the mode rational surfaces that occur in ideal MHD, marginal stability ($\omega^2 = 0$) when

$$\boldsymbol{k} \cdot \boldsymbol{B} = \frac{m}{r} B_\theta + k B_z = 0.$$

The nonlinear development of the tearing mode can lead to steady MAGNETIC RECONNECTION.

The sudden eruption of a solar FLARE suggests that the initial instability is due to an ideal MHD instability. However, the release of magnetic energy requires resistivity. Driving the field lines together in response to an ideal MHD instability means that reconnection and energy release can occur on a much faster timescale than the tearing mode timescale.

Thermal instabilities

The form of the optically thin plasma radiation in the solar corona and other astrophysical plasmas can drive thermal instabilities, also called radiative modes and condensation modes. The shape of an analytic fit to the optically thin radiation is shown in figure 3 as a function of the temperature at both constant density and constant pressure. Note that for the case of constant pressure the radiation decreases for temperatures in the range 10^4 K to 10^7 K. Thus, if the temperature in the corona decreases due to a perturbation, then the radiation will increase causing the plasma to cool further (Parker 1957). This thermal runaway will continue until the temperature drops below 10^4 K, which is incidentally the typical temperature of prominences. Thermal instabilities can be understood by examining the linearized energy equation. Two distinct forms of the thermal instability arise depending on the ratio of the sound travel time, τ_s, to the radiative timescale, $\tau_{\rm rad}$. If $\tau_s \ll \tau_{\rm rad}$, the thermal instability evolves isobarically. For a uniform equilibrium and perturbations of the form $f(x,t) = \mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\boldsymbol{r})+\sigma t}$, the dispersion relation for the isobaric thermal mode is

$$\sigma = \frac{\gamma}{\gamma - 1}\left(-\frac{(\boldsymbol{k}\cdot\boldsymbol{B})^2}{B^2}\frac{l^2}{\tau_{\rm cond}} + \frac{(2-\alpha)}{\tau_{\rm rad}}\right) \tag{16}$$

where the timescales are defined in table 1 and α is given in table 2. The isochoric limit, when $\tau_s \gg \tau_{\rm rad}$, gives

$$\sigma = (\gamma - 1)\left(-\frac{(\boldsymbol{k}\cdot\boldsymbol{B})^2}{B^2}\frac{l^2}{\tau_{\rm cond}} - \frac{\alpha}{\tau_{\rm rad}}\right). \tag{17}$$

Physically, these modes can be understood as follows. In the isobaric limit any thermal disturbances evolve much more slowly than the propagation of pressure variations. So sound waves can propagate to equalize the pressure changes before the temperature can evolve significantly. Hence, the modes evolve at constant pressure. This is the case at coronal temperatures. In the isochoric limit the thermal instability evolves so quickly that there is no time for sound waves to propagate away from the instability region. Thus, flows cannot be set up to equalize the pressure and so the density cannot change. Thus, the instability evolves at constant density.

Thermal instabilities are one mechanism proposed for the formation of cool, dense solar prominences. The hot corona begins to condense and a siphon flow sucks plasma from the CHROMOSPHERE into the corona in order to equalize the pressure.

Onset of convection

A plasma heated from below becomes unstable to convection when the temperature gradient exceeds a critical value. Neglecting all the dissipation mechanisms initially and the magnetic field, we can analyze the linearized MHD equations for an equilibrium pressure and density satisfying hydrostatic balance, the ideal gas law and a prescribed temperature profile $T_0(z)$, where z is the vertical coordinate. The local criterion for the onset of convection occurs when the temperature gradient exceeds the adiabatic value. Thus, instability sets in when

$$\frac{\mathrm{d}}{\mathrm{d}z}\left(\frac{p}{\rho^\gamma}\right) < 0 \tag{18}$$

so that entropy decreases with height. This may be expressed as

$$\frac{\mathrm{d}T}{\mathrm{d}z} < -\frac{\gamma - 1}{\gamma}\frac{g}{\mathcal{R}T}. \tag{19}$$

Thus, if the temperature decreases at a faster rate, then convective motions set in. (See the article on MAGNETIC BUOYANCY for a description of the instability and the inclusion of a magnetic field.)

The inclusion of dissipation, through viscosity and thermal conduction, severly complicates the stability analysis and analytical progress can be made by using the Boussinesq approximation. Here sound waves are filtered out and density variations are only included in

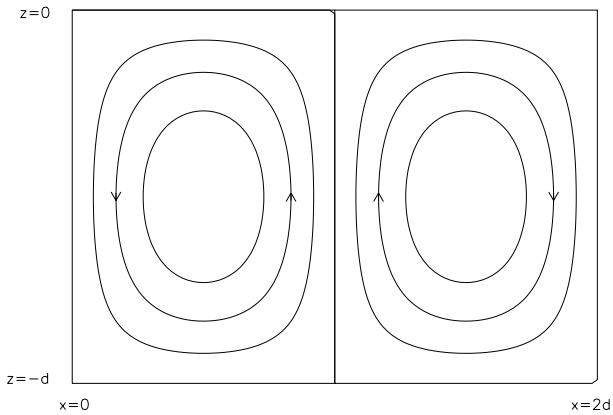

Figure 5. The streamlines for the convective motions that arises when the temperature gradient is large enough.

the gravitational term, as $\rho = \rho_0(1 + \alpha T_1)$, where T_1 is the perturbed temperature and α is the volume expansion coefficient. For the vertical velocity perturbation of the form

$$v_z(x, y, z, t) = V_z \, \mathrm{e}^{\sigma t} \, \mathrm{e}^{\mathrm{i}(k_x x + k_y y)} \sin \frac{\pi}{d} z$$

where d is the depth of the layer, stability depends on the value of the Rayleigh number

$$Ra = \frac{g\alpha \Delta T}{\kappa \nu}. \tag{20}$$

κ is the thermal conductivity, ν is the kinematic viscosity and ΔT is the temperature difference between the top and bottom of the layer. Setting $\sigma = 0$ in the dispersion relation gives the relation between Ra and the wavenumber k, defined by $k^2 = k_x^2 + k_y^2 + \pi^2/d^2$, for marginal stability. Instability occurs if Ra exceeds the critical value $Ra^* = 27\pi^4/4$. The marginal stability curve is shown in figure 4 and the streamlines, showing the cellular pattern of the plasma flow, are illustrated in figure 5.

White light images of the photosphere show granulation patterns giving clear evidence of convection. Larger scales of convection also occur, giving rise to supergranules and giant cells.

Kelvin–Helmholtz instability

The Kelvin–Helmholtz instability arises when there is a horizontal shear flow, $U(z)$, and the plasma density is stratified due to gravity. The classical Kelvin–Helmholtz instability is best illustrated for two plasmas of uniform density and uniform horizontal flows separated by an interface. The incompressible, linear equations are expressed in terms of the vertical velocity and solved. Assuming perturbations of the form

$$v_z = V_\pm \, \mathrm{e}^{\mathrm{i}(kx - \omega t) \mp kz}$$

where in region 1, $z > 0$, the upper sign is used and in region 2, $z < 0$, the lower sign is used. The two regions are matched at the perturbed interface using continuity of pressure and continuity of the normal displacement, ξ_z, where

$$\xi_z = \frac{v_z}{\omega - kU}.$$

The dispersion relation is

$$\rho_1(\omega - kU_1)^2 + \rho_2(\omega - kU_2)^2 = kg(\rho_2 - \rho_1) \qquad (21)$$

and the plasma is unstable if

$$(U_2 - U_1)^2 > \frac{g}{k}\frac{(\rho_2^2 - \rho_1^2)}{\rho_2\rho_1}. \qquad (22)$$

Thus, if k is sufficiently large, there is always a Kelvin–Helmholtz instability for any difference in the background flow speeds. Obviously, viscosity will stabilize these short-wavelength instabilities.

Kelvin–Helmholtz instabilities are likely to occur between the fast and slow plasma flows in the SOLAR WIND. In addition, the field lines separating the open field regions of CORONAL HOLES and the closed field regions of ACTIVE REGIONS will also experience these flow induced instabilities.

Magnetohydrodynamic Waves

Magnetohydrodynamic waves are found in a wide variety of astrophysical plasmas. They have been measured in plasma fusion devices and detected in the MAGNETOSPHERE OF EARTH, the SOLAR WIND and a number of magnetic structures seen in the Sun's atmosphere. In space plasmas their detection is often indirect, by matching measured properties (such as propagation speed or pressure variation) with theoretically deduced properties and correlations, although the magnetosphere and solar wind provide direct *in situ* measurements. A complication in the identification of magnetohydrodynamic waves in space plasmas has been the realization that generally such plasmas are strongly inhomogeneous, structured by magnetism, plasma density and temperature variations, or by plasma flows. This strong inhomogeneity brings about complications in the description of magnetohydrodynamic wave phenomena, with magnetic flux tubes and plasma flow tubes being of special interest. In the solar atmosphere, SUNSPOTS, SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES, CORONAL LOOPS and POLAR PLUMES are examples of flux tube structure, and oscillatory phenomena have been detected in all of them. Oscillations have also been detected in SOLAR PROMINENCES and generated by SOLAR FLARES.

Waves are the way in which information in a medium may be communicated from one region to another. In a gas communication can be achieved by sound waves, in the form of compressions and rarefactions of the medium which propagate at the sound speed c_s. For an ideal gas with equilibrium pressure p_0 and density ρ_0 the sound speed in a medium is given by

$$c_s = \left(\frac{\gamma p_0}{\rho_0}\right)^{1/2} \tag{1}$$

where γ is the ratio of specific heats. Magnetism introduces an additional speed, determined by the strength B_0 of the magnetic field and the plasma density ρ_0. This so-called Alfvén speed v_A is defined by

$$v_A = \left(\frac{B_0^2}{\mu\rho_0}\right)^{1/2} \tag{2}$$

where μ is the magnetic permeability of the medium. These two speeds determine the nature of wave propagation in magnetohydrodynamics.

The speeds c_s and v_A that characterize sound and magnetic effects are conveniently supplemented by the introduction of two further speeds, a slow speed c_t and a fast speed c_f, defined by

$$c_t^{-2} = c_s^{-2} + v_A^{-2} \qquad c_f^2 = c_s^2 + v_A^2. \tag{3}$$

The slow speed is evidently both sub-sonic and sub-Alfvénic; the fast speed c_f is super-sonic and super-Alfvénic. The slow speed c_t proves to be of particular significance in magnetic flux tubes and is accordingly sometimes referred to as the tube speed, although it is not the only speed of special significance in flux tubes (see below). The four speeds c_t, c_s, v_A and c_f arise in various ways in the description of magnetohydrodynamic wave phenomena, and their magnitudes may vary dramatically from application to application. For example, in a 2×10^6 K solar corona with a magnetic field strength of 10^2 G the sound speed is about 200 km s^{-1} and the Alfvén speed about 10^3 km s^{-1}, whereas in a solar photospheric flux tube both these speeds fall to about 10 km s^{-1}. The corresponding slow and fast speeds in the solar coronal illustration are 196 km s^{-1} and 1020 km s^{-1}, whereas in the photospheric flux tube these speeds are 7 km s^{-1} and 14 km s^{-1}, respectively.
